Being born with exstrophy per se does not result in childhood psychopathology. Children with exstrophy exhibit some tendency toward increased problems with acting out or lack of attainment of age-appropriate adaptive behavior (Montagnino et al, 1998; Reiner, 1999). Therefore, early counseling should be part of the standard management strategy for all children with the exstrophy-epispadias complex. In addition, patients and families should be encouraged to continue with psychological support as the child grows into adulthood.

KEY POINTS: BLADDER EXSTROPHY—PRIORITIES IN MANAGEMENT

- Size and quality of bladder template
- Extent of pubic diastasis and malleability of the pelvis
- Need for osteotomy
- Length and width of urethral plate
- Penile size
- Associated anomalies

EPISPADIAS

Epispadias varies from a mild glanular defect in a covered penis to the penopubic variety with complete incontinence in males or females. It is most commonly noted as a component of bladder and cloacal exstrophy.

Male Epispadias

Isolated male epispadias is a rare anomaly, with a reported incidence of 1 in 117,000 males. Most male epispadias patients (about 70%) have complete epispadias with associated incontinence (Gearhart and Jeffs, 1998). Epispadias consists of a defect in the dorsal wall of the urethra. The normal urethra is replaced by a broad, mucosal strip lining the dorsum of the penis extending toward the bladder, with potential incompetence of the sphincter mechanism. The displaced meatus is free of deformity, and occurrence of urinary incontinence is related to the location of the dorsally displaced urethral meatus (Gearhart and Jeffs, 1998). The displaced meatus may be found on the glans, on the penile shaft, or in the penopubic region. All types of epispadias are associated with varying degrees of dorsal chordee (Fig. 139-26). In penopubic or subsymphyseal epispadias, the entire penile urethra is opened and the bladder outlet may be large enough to admit the examining finger, indicating obvious gross incontinence (see Fig. 139-1D). To a lesser extent than in those with CBE, patients with epispadias have

Figure 139-26. Complete male epispadias.

a characteristic widening of the symphysis pubis caused by outward rotation of the innominate bones. This separation of the pubis causes divergent penopubic attachments that contribute to the short, pendular penis with dorsal chordee. Therefore, the penile deformity is virtually identical to that observed in bladder exstrophy. The reported male-to-female ratio of epispadias varies between 3:1 (Dees, 1949) and 5:1 (Kramer and Kelalis, 1982a).

Kramer and Kelalis (1982a) reviewed their experience with 82 male patients with epispadias. Penopubic epispadias occurred in 49 patients, penile epispadias in 21, and glanular epispadias in 12. Urinary incontinence was observed in 46 of 49 patients with penopubic epispadias, in 15 of 21 patients with penile epispadias, and in no patient with glanular epispadias. The goals of the treatment of complete male epispadias include creation of normal urinary control and establishment of a straight, cosmetically acceptable penis of adequate length that is functional for sexual intercourse.

Associated Anomalies

Anomalies associated with complete epispadias are usually confined to deformities of the external genitalia, diastasis of the pubic symphysis, and deficiency of the urinary continence mechanism. The only renal anomaly observed in 11 cases of epispadias was agenesis of the left kidney (Campbell, 1952). In a review by Arap and associates (1988), 1 case of renal agenesis and 1 ectopic kidney occurred among 38 patients.

The ureterovesical junction is inherently deficient in complete epispadias, and the incidence of reflux has been reported in a number of series to be between 30% and 40% (Kramer and Kelalis, 1982a; Arap et al, 1988). In a review by Ben-Chaim and colleagues (1995b) of a series of 15 patients with complete male epispadias treated at our institution, a lower rate of vesicoureteral reflux was noted compared with male patients with CBE (100% versus 82%, respectively); the rate of inguinal hernias (33%) was also significantly lower. A possible explanation for the lower incidence of reflux in complete male epispadias is that the pouch of Douglas is not as enlarged and deep. Therefore, the distal ureter enters the bladder in a more oblique fashion than in classic exstrophy (Gearhart and Jeffs, 1998).

Surgical Management

The objectives of repair of penopubic epispadias include achievement of urinary continence with preservation of the upper urinary tracts and the reconstruction of cosmetically acceptable genitalia. The surgical management of incontinence in penopubic epispadias is virtually identical to that in closed bladder exstrophy.

Young (1922) reported the first cure of incontinence in a male patient with complete epispadias. Since this initial report, continence after surgical reconstruction has progressively improved (Burkholder and Williams, 1965; Kramer and Kelalis, 1982a; Arap et al, 1988; Peters et al, 1988; Mollard et al, 1998). In patients with complete epispadias and good bladder capacity, epispadias and bladder neck reconstruction can be performed in a single-stage operation. Urethroplasty formerly was performed after bladder neck reconstruction (Kramer and Kelalis, 1982a; Arap et al, 1988). However, improvements in bladder capacity in the small bladder associated with exstrophy (Gearhart and Jeffs, 1989a) and that associated with epispadias (Peters et al, 1988) have led us to perform urethroplasty and penile elongation before bladder neck reconstruction. A small, incontinent bladder with reflux is hardly an ideal situation for bladder neck reconstruction and ureteral reimplantation. Before bladder neck reconstruction there was an average increase in bladder capacity of 95 mL within 18 months after epispadias repair in the patients with an initial small bladder capacity and a continence rate of 87% after the continence procedure (Peters et al, 1988). In a series by Ben-Chaim and colleagues (1995b) composed exclusively of patients with complete male epispadias, bladder capacity increased by an average of 42 mL within 18 months after urethroplasty. Nine (82%) of 11 patients were dry day and night after an average of 9 months.

In epispadias, as in bladder exstrophy, bladder capacity is the predominant indicator of eventual continence (Ritchey et al, 1988). Arap and coworkers (1988) reported higher continence rates in patients who had an adequate bladder capacity before bladder neck reconstruction than in those with inadequate capacity (71% vs. 20%, respectively). In addition, in Arap's group of patients with complete epispadias, most obtained continence within 2 years, similar to results in patients with CBE.

A firm intrasymphyseal band typically bridges the divergent symphysis, and an osteotomy is not usually performed. The Young-Dees-Leadbetter bladder neck plasty, Marshall-Marchetti-Krantz suspension, and ureteral reimplantation are performed when the bladder capacity reaches approximately 100 mL, which usually occurs between 4 and 5 years of age when the child is ready to be dry. Genital reconstruction procedures in epispadias and exstrophy are similar. The following reconstructive maneuvers must take place: release of dorsal chordae and division of the suspensory ligaments; dissection of the corpora from their attachments to the inferior pubic ramus; lengthening of the urethral groove; and lengthening of the corpora, if needed, by incision and anastomosis or grafting or by medial rotation of the ventral corpora in a more downward direction.

Urethral reconstruction in complete epispadias has been performed in many ways. A transverse island flap was used by Monfort and colleagues (1987). The urethra, once reconstructed, can be positioned between and below the corpora (Cantwell, 1895; Ransley et al, 1989; Gearhart et al, 1992, 1995c). Mitchell and Bāgli (1996) reported their experience with a complete penile disassembly technique, and a multicenter experience was reported in a total of 17 patients from four institutions (Zaontz et al, 1998). Chordee was reliably corrected, erectile function was preserved, the urethra was eventually situated in a cosmetic fashion, and satisfactory cosmesis was achieved. Caione and Capozza (2001) reported on their experience with the use of penile disassembly and reapproximation of the perineal muscle complex for the management of boys with epispadias, indicating the ability to achieve continence without the need for additional bladder neck reconstruction. A recent small series by Kibar and colleagues (2009a) of patients with complete epispadias showed that complications with use of the disassembly repair were in the acceptable range. Unlike the use of this in the exstrophy group, there was no ischemia of the glans or corpora. However, most patients required additional surgery because hypospadias was created in a number of patients. Repair of this hypospadias can be challenging and can have high complication rates (Berrettini et al, 2011). Cervellione and colleagues (2010) did report on 4 patients who underwent penile disassembly or radical soft-tissue mobilization (Kelly procedure) who had significant corporeal loss after surgery. Ransley and Surer and associates reported excellent results using the modified Cantwell-Ransley procedure, saving cavernocavernostomy for patients with very severe chordee and especially those in the older age group (Kajbafzadeh et al, 1995; Surer et al, 2000). For detailed description of the surgical reconstruction, see the previous discussion in the section on bladder exstrophy.

It was formerly thought that the effect of urethral lengthening and prostatic enlargement might be significant in complete epispadias by increasing outlet resistance if continence was not perfect as the child became older. Earlier in a series by Arap and associates (1988), the establishment of continence had no relation to puberty and usually occurred within 2 years, usually preceding puberty by several years. In the series reported by Ben-Chaim and coworkers (1995b), as stated previously, all patients obtained daytime continence at a mean of 9 months after bladder neck reconstruction, and 9 (82%) of 11 patients attained total day and night continence. All patients voided spontaneously. After a mean follow-up of 7 years, all patients maintained normal upper tracts and kidney function. All of them had cosmetically pleasing genitalia, as judged by parents, patients, and physicians, and experienced normal erections. A 36-year-old patient was married and had fathered three children. Many of the patients were younger than 16 years and had not yet become sexually active. Results of urethroplasty in epispadias have been reported in a number of publications (Mesrobian et al, 1986;

Ransley et al, 1989; Kajbafzadeh et al, 1995; Zaontz et al, 1998). In a modern series of modified Cantwell-Ransley repairs reported by Surer and colleagues (2000), the incidence of postoperative fistula in the 3-month period after surgery was 19%, and the incidence of urethral stricture formation was less than 10%. Catheterization and cystoscopy could easily negotiate the neourethral channel in all patients who underwent a modified Cantwell-Ransley epispadias repair. In another modern series reported by Mollard and coworkers (1998), the continence rate was 84% and the fistula rate was less than 10%. In Mollard's series with long-term follow-up, patients had normal erections; the vast majority had regular sexual intercourse, and most had normal ejaculation or had fathered children. Most of Surer's patients were quite young, and assessment of genital reconstruction must be deferred until these patients are sexually mature and active (Surer et al, 2000). Hafez and Helmy (2011) reported on three patients with isolated penopubic epispadias who underwent postpubertal reconstruction using penile disassembly, indicating good cosmesis with a meatus at the tip.

Although many methods of epispadias repair exist, meticulous follow-up of the urethra, appropriate selection of patients, and surgical experience remain the milestones of success. Lastly, Ransley and colleagues (Kajbafzadeh et al, 1995) obtained very good results using a modified Cantwell-Ransley repair in a large number of patients with epispadias. The fistula rate was 4%, and the urethral stricture rate was 5.3%. Baird and colleagues (2005b) reported on 129 boys who underwent a modified Cantwell-Ransley repair. Of this group, 32 had penopubic epispadias. Twenty-four procedures were primary repairs and eight were secondary repairs. Urethrocavitaneous fistula occurred in 13% of primary and 25% of secondary repairs. A urethral stricture occurred in one patient.

Achievement of urinary continence in patients with isolated epispadias is summarized in Table 139-4. A majority of these patients underwent reconstruction by means of a modified Young-Dees-Leadbetter bladder neck plasty. Urinary continence was obtained in 82% of male patients (Ben-Chaim et al, 1995b). As in the exstrophy population, repair of the epispadiac deformity results in an increase of outlet resistance and possible increase in bladder capacity before bladder neck reconstruction. Although both complete epispadias and bladder exstrophy patients achieve improvement in bladder capacity after epispadias repair, the mean increase in overall capacity is higher in those with complete epispadias. This increase in bladder capacity may account for increased continence in this group compared with the CBE population. Clinically, these bladders are more supple, easier to mobilize, and more amenable to bladder neck reconstruction. Ben-Chaim and colleagues (1995b) reported that the mean time to initial continence after bladder neck reconstruction was 90 days in patients with complete male epispadias compared with 110 days in those with bladder exstrophy. These results suggest that for patients with complete epispadias, bladder capacity before reconstruction and the rate of achieving continence afterward are better than in exstrophy. The reason might be that the bladder is not exposed in utero and does not have any scarring from prior closure; therefore its potential for expansion is higher.

In a different approach to the treatment of incontinence associated with epispadias reported by Duffy and Ransley (1998), 12 boys aged 3 to 7 years underwent endoscopic submucosal injection of plastic microspheres. All patients had undergone a modified Cantwell-Ransley epispadias repair before injection. The procedure was performed 24 times, with a total volume of 83 mL of material injected into 59 sites in the posterior urethra. Mean follow-up was 10.8 months. Three patients (25%) were rendered completely dry, the degree of incontinence was improved in 6, and there was no change in 3. The authors offered this approach as an alternative to bladder neck reconstruction in patients with primary epispadias. Ben-Chaim and coworkers (1995a) reported that submucosal injection of collagen in the bladder neck area can have a role in improving stress incontinence when the patient with complete epispadias has incomplete urinary control or as an adjunct after bladder neck reconstruction. In a recent study by Kibar and colleagues (2009b) of complete epispadias, 1 patient out of 12 was continent after bladder neck injection.

TABLE 139-4 Urinary Continence after Bladder Neck Reconstruction (BNR) in Patients with Complete Epispadias

Percent with surgically corrected incontinence	0%	87%	83%	77%	70%	

*All complete female epispadias cases.

Kramer and associates (1986) reported the success of genital reconstruction in epispadias, with good long-term follow-up ending with a straight penis angled downward in almost 70% of patients, with normal erectile function. Of this group, 80% had satisfactory sexual intercourse, and of 29 married patients, 19 had fathered children. These results were mirrored in the long-term follow-up study of [Mollard and associates \(1998\)](#).

A carefully constructed and well-planned approach to the management of urinary incontinence in genital deformities associated with complete epispadias should provide a satisfactory cosmetic appearance, normal genital function, and preservation of fertility potential in most patients.

Female Epispadias

Female epispadias is a rare congenital anomaly; it occurs in 1 of every 484,000 female patients ([Gearhart and Jeffs, 1998](#)) ([Fig. 139-27](#)). We use the classification of [Davis \(1928\)](#), which describes three degrees of epispadias in female patients ([Fig. 139-28A to D](#)). In the least severe degree of epispadias, the urethral orifice simply appears patulous. In intermediate epispadias, the urethra is dorsally split along most of the urethra. In the most severe degree of epispadias, the urethral cleft involves the entire length of the urethra and sphincteric mechanism and the patient is rendered incontinent ([Fig. 139-28](#)). The genital defect is characterized by a bifid clitoris. The mons is depressed in shape and coated by a smooth, glabrous area of skin. Beneath this area, there may be a moderate amount of subcutaneous tissue and fat, or the skin may be closely applied to the anterior and inferior surface of the symphysis pubis. The labia minora are usually poorly developed and terminate anteriorly at the corresponding half of the bifid clitoris, where there may be a rudiment of a preputial fold. These external appearances are most characteristic: on minimal separation of the labia, one sees the urethra, which may vary considerably, as mentioned previously. The symphysis pubis is usually closed but may be represented by a narrow fibrous band. The vagina and internal genitalia are usually normal. Because the external appearance changes may be minimal, some children are identified only because of persistent incontinence ([Yeni et al, 2004](#); [Shetty et al, 2011](#)).

Figure 139-27. Complete female epispadias.

Associated Anomalies

The ureterovesical junction is inherently deficient in patients with epispadias, and the ureters are often laterally placed in the bladder with a straight course so that reflux occurs. The incidence of reflux is reported to be 30% to 75% ([Kramer and Kelalis, 1982b](#); [Gearhart et al, 1993a](#)). Because there is no outlet resistance, the bladder is small and the wall is thin. After initial reconstruction, the urethral resistance that is created allows the bladder to grow and develop to an acceptable capacity for bladder neck reconstruction.

Figure 139-28. A, Normal female anatomy. B, Vesicular epispadias—urethra mainly normal but relation to clitoris altered. C, Subsphyseal epispadias—defect in anterior wall of urethra for about one half its length. D, Retrosymphyseal epispadias—defect in anterior wall of entire urethra. Sphincter is usually involved. SYM, symphysis. (Used with permission of Brady Urological Institute.)

Surgical Objectives

Objectives for repair of female epispadias parallel those devised for male patients: (1) achievement of urinary continence, (2) preservation of the upper urinary tracts, and (3) reconstruction of functional and cosmetically acceptable external genitalia.

Operative Techniques

With the patient in the lithotomy position, the defect of the female epispadias with incontinence is apparent (Fig. 139-29A). The two halves of the clitoris are widely separated, and the roof of the urethra is cleft between the 9 o'clock and 3 o'clock positions. The smooth mucosa of the urethra tends to blend cephalad with the thin, hairless skin over the mons. The urethral incision is begun at the cephalad extent of the vertical incision at the base of the mons and is brought inferiorly through the full thickness of the urethral wall at the 9 o'clock and 3 o'clock positions

(Fig. 139-29B). Sutures can be placed in the urethra to permit downward traction on the urethra so that the roof of the urethra is excised to a level near the bladder neck (Fig. 139-29C). Often, one finds the dissection proceeding under the symphysis. An inverting closure of the urethra is then performed over a 10-Fr Foley catheter. Suturing is begun near the bladder neck and progresses distally until closure of the neourethra is accomplished (Fig. 139-29D). Attention is then given to denuding the medial half of the bifid clitoris and the labia minora so that proper genital coaptation can be obtained.

After this is done, fat from the mons and subcutaneous tissue can be used to cover the suture line and obliterate the space in front of the pubic symphysis (Fig. 139-29E and F). The two halves of the clitoris and labia minora are brought together using interrupted sutures of 6-0 polyglycolic acid. The corpora may be partially detached from the anterior ramus of the pubis to aid in the urethral closure. Also, bringing these tissues together may contribute by adding resistance to the urethra. Mons closure is further aided by

Figure 139-29. A, Typical appearance of female epispadias with initial incisions outlined. B, Excision of the glabrous skin of the mons. C, Tapering of the urethra with a dorsal resection of a wedge of tissue. D, Reconstruction of the urethra over a catheter with running suture. E and F, Medial aspect of the labia minora and clitoris. G, Initial layer of mons closure. H, Approximation of the labia minora over the urethral reconstruction. I, Second layer of mons closure. J, Creation of clitoral hood. K, Completion of mons closure. (© Brady Urological Institute.)

mobilizing subcutaneous tissue laterally and bringing it medially to fill any prior depression that remains (Fig. 139-29G). The subcutaneous layer is closed with 4-0 polyglactin suture in an interrupted fashion (Fig. 139-29H). The skin is closed with interrupted sutures of 6-0 polypropylene (Fig. 139-29I to K).

A 10-Fr catheter is left indwelling for 5 to 7 days. Should the patient undergo simultaneous bladder neck reconstruction, a Foley catheter is not left in the urethra and the patient is placed in the supine position for the abdominal part of the procedure.

Achievement of a satisfactory cosmetic appearance of the external genitalia and urinary continence in the female child with epispadias represents a surgical challenge. Many operations have been reported to control continence in the epispadias group, but the results are disappointing. These procedures include transvaginal plication of the urethra and bladder neck, muscle transplantations, urethra twisting, cauterization of the urethra, bladder flap, and Marshall-Marchetti vesicourethral suspension (Stiles, 1911; Davis, 1928; Marshall et al, 1949; Gross and Kresson, 1952). These procedures may increase urethral resistance, but they do not correct incontinence or the malformed anatomy of the urethra, bladder neck, and genitalia.

The challenge of the small bladder in the female epispadias patient is comparable to a situation seen in patients with a closed exstrophy. The small, incontinent bladder, with or without reflux, is hardly an ideal setting for a successful bladder neck reconstruction and ureteral reimplantation. A third of all incontinent epispadias patients have a bladder capacity of less than 60 mL, in our experience and that of Kramer and Kelalis (1982b). Bladder augmentation, injection of polytetrafluoroethylene (Teflon) in the bladder neck area, and simultaneous bladder neck reconstruction and bladder neck augmentation have been offered as a solution to this challenge. However, primary closure of the epispadiac urethra in children with closed exstrophy was found to increase bladder capacity without causing hydronephrosis, and this approach has been applied to male and female patients with epispadias (Peters et al, 1988; Gearhart and Jeffs, 1989a; Ben-Chaim et al, 1995b). Although we typically perform urethral and genital reconstruction at 6 months to 1 year of age, we advocate delaying bladder neck reconstruction until the child is 4 to 5 years old. Not only does this delay allow the bladder to increase in capacity, it also allows the child to accept essential instructions for toilet training, which is critical to achieving satisfactory continence in the postoperative state. Data from de Jong and colleagues (2000) combined a standard exterior genitoplasty plus urethroplasty with a percutaneous bladder neck suspension. The authors felt the suspension moved the bladder neck into an intra-abdominal position. In this small series, one patient was dry and voiding, two required bladder neck bulking agents, and one was on CIC. In another small series from India, Bhat and colleagues (2008) performed a urethroplasty and the perineal musculature was double-breasted over the urethral closure from the bladder neck distally. Bhat and coauthors reported impressive results with two totally continent, one partially continent, and one continent patient after bladder neck reconstruction.

Surgical Results

The continence rate of 87.5% in our female patients is comparable to that of Hanna and Williams (1972), who found a 67% continence rate in female patients with good bladder capacity, and that of Kramer and Kelalis (1982b), who reported an 83% continence rate in patients with adequate bladder capacity. All of our patients seen for primary treatment have achieved a capacity in excess of 80 mL (see Table 139-4).

Hendren (1981) and Kramer and Kelalis (1982b) showed that genitourethral reconstruction can be accomplished with satisfactory results. At our institution, patients who underwent prior urethral and genital reconstruction had a mean bladder capacity at bladder neck reconstruction of 121 mL, making the bladder suitable for the reconstruction and eventual continence without the use of augmentation cystoplasty or need for intermittent catheterization.

The time interval to achieve continence in our patients was a mean of 18 months for those who underwent genitourethral and bladder neck reconstruction in one procedure and 23 months for those who underwent preliminary urethroplasty and genital reconstruction after bladder neck reconstruction. In a series by Klauber and Williams (1974), the mean interval to acceptable continence was 2.25 years. Also, in a series by Kramer and Kelalis (1982b), some patients became continent within a short period, whereas complete continence was delayed for several years in others. The time delay for achieving continence may represent increased pelvic muscular development, as suggested by Kramer and Kelalis (1982b). In regard to the interval to continence, no advantage appears to be gained by preliminary urethroplasty. However, we believe that the advantage gained by increased bladder capacity at the time of bladder neck reconstruction outweighs any advantage gained by a combined approach. Suson and colleagues (2013) compared 22 girls with complete female epispadias to 23 girls with CBE. Although girls with female epispadias had reconstruction at a later age than those with CBE, bladder growth rate did not differ between the two groups. Neither group had any difference in number of surgical procedures, development of continence with or without the need for bladder neck reconstruction, or eventual need for continent urinary diversion.

CLOACAL EXSTROPHY

Cloacal exstrophy includes a spectrum of abnormalities but is primarily an anterior abdominal wall defect. A reported incidence of 1:200,000 to 1:400,000 makes this one of the rarer urologic abnormalities (Hurwitz et al, 1987). Although prior reports have suggested a male-to-female ratio of 2:1 (Gearhart and Jeffs, 1998), a large study by Boyadjiev and colleagues (2004a) indicated that the sex ratio may be 1:1. Most cases are sporadic, and isolated incidences of unbalanced translocations have been reported to be potentially causative (Thauvin-Robinet et al, 2004); however, one report noted recurrence in siblings, perhaps indicating a more multifactorial etiology. Recent reports have indicated a greater incidence of cloacal exstrophy associated with maternal exposure to cigarette smoke (Gambhir et al, 2008). It is interesting to note that mothers of infants with cloacal exstrophy were more compliant with preconceptional folate use. Associated defects of the neurospinal axis, intestinal tract, and urogenital and skeletal systems are frequently noted. When neurospinal defects and omphalocele coexist with cloacal exstrophy, the term *OEIS complex* (omphalocele, exstrophy, imperforate anus, spinal defects) has been used (Keppler-Noreuil, 2001). Advances in the care of critically ill children has resulted in most infants with cloacal exstrophy surviving into adulthood. The focus of management has therefore shifted to improving QoL (Mathews et al, 1998).

Anatomic Considerations

The classic constellation of anomalies that are noted in children with cloacal exstrophy includes exstrophy of the bladder, complete phallic separation, wide pubic diastasis, exstrophy of the terminal ileum between the two halves of the bladder, a rudimentary hindgut, imperforate anus, and the presence of an omphalocele. Many children have associated spinal defects, and various lower extremity malformations may be noted (Loder and Dayioglu, 1990; Jain and Weaver, 2004). The urogenital anomalies in cloacal exstrophy are similar to those seen with CBE (see earlier), although they are typically of greater severity.

Neurospinal Abnormalities

Abnormalities of the spinal cord or vertebral column or both have been noted in 85% to 100% of children with cloacal exstrophy (Appignani et al, 1994; McLaughlin et al, 1995). Although most patients have lumbar myelodysplasia (80%), thoracic defects may be noted in 10%, with the remaining having sacral defects. In a large

series of 34 patients from a single center with cloacal exstrophy and associated spinal defects, Mathews and coworkers (1998) noted lipomeningocele in 17, myelomeningocele in 8, and spina bifida and isolated cord tethering in 7 and 2 patients, respectively. The nearly universal incidence of spinal abnormalities has led some authors to suggest MRI for all patients with a diagnosis of cloacal exstrophy (Cohen, 1991). Spinal ultrasound evaluation, which is easily performed, has been noted to be comparable to MRI for the diagnosis of spinal anomalies in infants with cloacal exstrophy (Dick et al, 2001). Karrer and colleagues (1988) noted that only 1 in 5 children with spinal dysraphism noted on ultrasonography had a sacral abnormality visible on the skin surface.

The embryologic basis for the neurospinal defects associated with cloacal exstrophy has been postulated to be secondary to disruption of the tissue of the dorsal mesenchyme rather than failure of neural tube closure (McLaughlin et al, 1995). Alternatively, it has been suggested that the defects that lead to the formation of cloacal exstrophy may lead to the developing spinal cord and vertebrae being pulled apart (Cohen, 1991). Functional deficits can range from patients who have almost normal sensation of the pelvis and lower extremity to patients who are wheelchair bound. The presence of a clinically significant neurologic anomaly was found to negatively affect the development of continence (Husmann et al, 1999). Only 1 of 13 neurologically impaired patients in this series developed voided continence.

The neuroanatomic dissections performed by Schlegel and Gearhart (1989) further indicate that the neuroanatomic landmarks in the infant with cloacal exstrophy are different from those in the normal newborn, with the autonomic bladder innervation being derived from a more medial location (Fig. 139-30). This potentially

puts the nerve supply in jeopardy during initial bladder dissection and reconstruction and can potentially leave the bladder neuropathic after reconstruction (Husmann et al, 1999). Innervation to the duplicated corporeal bodies arises from the sacral plexus, travels in the midline, perforates the pelvic floor, and courses medially to the hemibladders (Schlegel and Gearhart, 1989). Innervation abnormalities were also noted at a histologic level in the studies by Rosch and colleagues (1997). When compared with those in patients with bladder exstrophy, the neural elements identified on immunohistochemical evaluation were found to show significant structural abnormalities.

Skeletal System Abnormalities

Anomalies of the skeletal system are universally noted in children with cloacal exstrophy. The pubic diastasis noted in the exstrophy-epispiadias complex are seen at their most extreme with cloacal exstrophy. Sponseller and associates (1995), studying patients with the exstrophy complex, noted that the posterior segment of the pelvis in children with cloacal exstrophy was angled farther posteriorly and there was a greater likelihood of asymmetry between the two sides. Similarly, the anterior segment of the pelvis had more severe degrees of external rotation. The actual length of the bone segments, however, was similar between those with cloacal and classic exstrophy. The interpubic distance (diastasis) in children with cloacal exstrophy was noted to be almost twice that in children with CBE. Malformation of the sacroiliac joints and side-to-side asymmetry were also noted. Most children with cloacal exstrophy therefore require osteotomy for successful reconstruction. Stec and colleagues (2003) noted that microscopically the bones in

Figure 139-30. Internal view of a patient with cloacal exstrophy. Pudendal vessels, nerves, and other vessels and autonomic innervations of the corporeal bodies are demonstrated. Internal structures of the pelvis along with duplication of the vena cava in this dissected specimen are also shown.

children with cloacal exstrophy were similar to those in normal controls and were developing at a similar rate, indicating that the potential for growth was also similar.

Vertebral anomalies not associated with myelodysplasia were noted in 8 of 37 children with cloacal exstrophy (Mathews et al, 1998). Loder and Dayioglu (1990) noted vertebral anomalies in 3 of 5 children with cloacal exstrophy. Absence or shortening of limbs was also noted, as were clubfoot malformations. Skeletal and limb anomalies were also reported by Diamond (1990) in 12% to 65% of patients. The vast majority were clubfoot deformities, although absence of feet, severe tibial or fibular deformities, and congenital hip dislocations were commonly noted in this group of patients. A similar high incidence of foot abnormalities and greater than normal abduction of the hips was noted in a study by Greene and coworkers (1991).

Intestinal Tract Abnormalities

Gastrointestinal tract anomalies occur in virtually all patients with cloacal exstrophy. In Diamond's series (1990), the incidence of omphalocele was 88%, and most other series report an incidence of 95% or greater. In the series reported by Mathews and colleagues (1998), 100% of patients had an omphalocele. Omphaloceles do vary in size and usually contain small bowel or liver or both. Immediate closure of the omphalocele defect in the newborn period is advised to prevent subsequent rupture.

Hurwitz and colleagues (1987), in a large review of cloacal exstrophy patients, reported a 46% incidence of associated gastrointestinal tract anomalies, with malrotation, duplication anomalies, and anatomically short bowel occurring with equal frequency. A hindgut remnant of varying size is also noted in most patients. Hurwitz noted a 23% incidence of short gut syndrome, which is compatible with the 25% incidence reported by Diamond (Hurwitz et al, 1987; Diamond, 1990). It now seems well accepted that short gut syndrome may occur in the presence of normal small bowel length, suggesting absorptive dysfunction and emphasizing the absolute need to preserve as much large bowel as possible. If not used for incorporation into the fecal stream, the hindgut remnant may be preserved for use in urogenital tract reconstruction (Mathews et al, 1998). Modern techniques have reduced the incidence of short gut syndrome in the majority of patients (Sawaya et al, 2010).

Genitourinary Abnormalities

Müllerian anomalies have been frequently noted in conjunction with cloacal exstrophy. The most commonly reported müllerian anomaly was uterine duplication, seen in 95% of patients (Diamond, 1990). The vast majority of these patients had partial uterine duplication, predominantly a bicornate uterus. Vaginal duplication occurred in 65% of patients, and vaginal agenesis was seen in 25% to 50% of patients. In a report by Hurwitz and colleagues (1987), cases of complete duplication of the uterus and fallopian tubes associated with both vaginal duplication and vaginal agenesis were noted. Gearhart and Jeffs (1991b) recommended preservation of all müllerian duplication anomalies for possible use in reconstructing the lower urinary tract.

Upper urinary tract anomalies occurred in 41% to 60% of patients in Diamond's review (1990). The most common anomalies were pelvic kidney and renal agenesis, both occurring in up to one third of patients. Hydronephrosis and hydroureter were common, occurring in one third of patients. Multicystic dysplastic kidneys and fusion anomalies were seen less frequently. Ectopic ureters draining to the vasa in the male and into the uterus, vagina, or fallopian tubes in the female were also reported (Diamond, 1990). A similar incidence of upper tract defects was noted by Mathews and colleagues (1998). Ureteral duplication, congenital stricture, and megaureter were also reported.

Genital anomalies in the male have typically included complete separation of the two phallic halves and accompanying separation of the scrotal halves. Asymmetry of these structures can also be seen and can provide additional challenges to successful reconstruction.

Figure 139-31. Coding grid used to describe cloacal exstrophy and its variants. B1_E everted bowel; O, omphalocele; HBL_E, hemibladder; HG, hindgut; HP, hemiphallus. (From Manzoni GA, Ransley PG, Hurwitz RS. Cloacal exstrophy and cloacal exstrophy variants: a proposed system of classification. *J Urol* 1987;138:1065-8.)

Testes may be noted in the scrotum but are frequently noted to be undescended, and associated inguinal hernias are a common finding. Girls typically have widely divergent clitoral halves.

The lower urinary tract is typically composed of two exstrophied hemiblasters flanking the exstrophied intestinal segment. Each bladder half usually drains the ipsilateral ureter and is closely related to the ipsilateral phallic segment. Variations of anatomy, however, are frequently seen, and every patient has unique anatomic features.

Additional System Anomalies

Life-threatening cardiovascular and pulmonary anomalies are rarely seen in cloacal exstrophy. Reported cases included two patients with cyanotic heart disease and one with aortic duplication. A bilobed lung was reported in two patients and an atretic right upper lung in one. Also, Schlegel and Gearhart (1989) reported caval duplication in their anatomic dissection of a patient with cloacal exstrophy.

Because of the complexity and the multisystem nature of cloacal exstrophy, Hurwitz and coauthors (1987) have devised a grid for the clarification of anatomy in each patient and to permit planning for reconstruction (Fig. 139-31). This permits the standard form of cloacal exstrophy to be separated from variants and allows the soft-tissue components of the defect to be described systematically.

Cloacal Exstrophy Variants

Cloacal exstrophy usually includes an open and everted intestinal segment situated between two hemiblasters, an omphalocele, and a blind-ending tailgut with an imperforate anus. The pubic symphysis and the rectus muscles are widely separated. The phallus is bifid, and the scrotum or labia are split and laterally displaced. In girls the vagina is bifid with two uteri. Given that cloacal exstrophy encompasses abnormalities of the genitourinary, gastrointestinal, and musculoskeletal systems, and often the neurologic system, it is not surprising that a wide range of variants from the classic presentation have been reported. The treatment of cloacal exstrophy has evolved from palliation of an almost universally fatal disorder into complex genitourinary and gastrointestinal reconstruction and a near-normal life span.

Of six cases reported by Lowentritt and colleagues (2005) with cloacal variants, five were skin covered and one involved duplication of the bowel and hemiblasters. Cases of cloacal exstrophy are challenging in their surgical management, and the variations of the complex add to the difficulties of initial diagnosis and management. Only by using a combination of genitograms, retrograde ureterograms, and bowel continence studies was it possible to

understand the complex anatomy of the patients in these groups. It is interesting to note that three patients had no spinal abnormalities and one had spina bifida occulta. Three patients in this group had innervation of the pelvic floor, enabling successful Pena procedures in two, with the third patient awaiting the procedure. Cloacal variants have a lower incidence of spinal abnormalities and a higher rate of fecal continence compared with their classic presentations. Overall, these patients had a low incidence of severe comorbid conditions. Therefore, appropriate treatment of these genitourinary malformations can significantly affect and improve QoL.

Prenatal Diagnosis

Since the initial description of cloacal exstrophy in the early 1980s, further refinements in its prenatal ultrasound diagnosis have occurred (Meizner and Bar-Ziv, 1985). These authors indicated that the three main criteria used to identify the diagnosis were a large midline infraumbilical anterior abdominal wall defect, lumbosacral myelomeningocele, and failure to visualize the urinary bladder. Chitrit and colleagues (1993) reported the diagnosis of monozygotic twins with cloacal exstrophy detected during antenatal ultrasound screening. Since these initial reports, there have been only occasional case reports of prenatal diagnosis of cloacal exstrophy, and only 15% of patients with this anomaly have been diagnosed by prenatal ultrasonography, according to the literature. With the marked improvements in survival of patients with cloacal exstrophy in the last 20 years and the common application of fetal ultrasonography, early diagnosis may permit appropriate prenatal counseling for parents and expedite postnatal care.

Austin and colleagues (1998) reviewed 20 patients with this abnormality, expanded on the diagnostic findings, and proposed major and minor criteria for the prenatal ultrasound diagnosis of cloacal exstrophy, based on the frequency of occurrence rather than the severity of individual findings. A criterion was considered major if it was present in more than 50% of cases. The gestational age at diagnosis of cloacal exstrophy ranged from 15 to 32 weeks (mean, 22 weeks). Major diagnostic criteria included nonvisualization of the bladder in 91%, a large midline infraumbilical anterior wall defect or a cystic anterior wall structure in 82%, an omphalocele in 77%, and a myelomeningocele in 68%. Minor criteria included lower extremity defects in 23%, renal anomalies in 23%, ascites in 41%, widened pubic arches in 18%, narrow thorax in 9%, hydrocephalus in 9%, and a single umbilical artery in 9%. Hamada and coauthors (1999) reported a single case in which ultrasonography revealed a wavy cordlike segment of soft tissue protruding from the anterior abdominal wall of the fetus below the umbilicus. This was found to be prolapsed terminal ileum, which resembled the trunk of an elephant. The authors suggested that this sonographic image be added to the criteria described by Austin and associates (1998) for making a prenatal diagnosis of cloacal exstrophy.

MRI has been used successfully for the prenatal evaluation of cloacal exstrophy (Chen et al, 2008). In conjunction with ultrasonography, excellent definition of anatomy can now be obtained. MRI was found to be superior to ultrasonography when a normal bladder is not identified (Calvo-Garcia et al, 2013). In addition, MRI was able to definitively identify the omphalocele, gender ambiguity, and spinal defect that were not easily defined with ultrasonography (Goto et al, 2012).

Antenatal diagnosis now permits parental counseling and postnatal management. Extensive parental counseling regarding the significant anatomic anomalies that constitute the complex is appropriate in conjunction with psychological support. Prenatal identification of cloacal exstrophy should permit planned maternal-fetal transfer to a center with subspecialty experience for perinatal management (Keppler-Noreuil et al, 2007).

SURGICAL RECONSTRUCTION OF CLOACAL EXSTROPHY

The initial successful reconstruction of cloacal exstrophy was reported by Rickham and Johnston (Rickham, 1960). Survival in

BOX 139-1 Modern Functional Reconstruction of Cloacal Exstrophy

IMMEDIATE NEONATAL ASSESSMENT

Evaluate associated anomalies
Decide whether to proceed with reparative surgery

FUNCTIONAL BLADDER CLOSURE (SOON AFTER NEONATAL ASSESSMENT)

One-Stage Repair (Few Associated Anomalies)

Excision of omphalocele
Separation of cecal plate from bladder halves
Joining and closure of bladder halves and urethroplasty
Bilateral anterior innominate and vertical iliac osteotomy
Terminal ileostomy and colostomy
Genital revision if needed

Two-Stage Repair

First Stage (Newborn Period)

Excision of omphalocele
Separation of cecal plate from bladder halves
Joining of bladder halves
Gonadectomy in male with unreconstructible phallus
Terminal ileostomy and colostomy

Second Stage

Closure of joined bladder halves and urethroplasty
Bilateral anterior innominate and vertical iliac osteotomy
Genital revision if needed

ANTI-INCONTINENCE AND REFLUX PROCEDURE (AGE 4 TO 5 YEARS)

Bladder Capacity ≥ 100 mL (Small Select Group of Patients)

Young-Dees-Leadbetter bladder neck reconstruction
Bilateral Cohen ureteral reimplantations
Bowel and/or stomach segment used to augment bladder, or
Continent diversion with abdominal or perineal stoma

VAGINAL RECONSTRUCTION

Vagina constructed or augmented using colon, ileum, of full-thickness skin graft

the 1970s remained at about 50%; however, the institution of intensive postnatal care led to improvement in survival in the 1980s to almost 100%. Where access to subspecialty care is limited, survival can be severely compromised.

Evaluation and Management at Birth

Immediate management is directed to the medical stabilization of the infant. Complete physical examination and determination of the various anatomic defects present allow short- and long-term management strategies to be created (Box 139-1). This initial planning stage should include decisions about gender assignment. The bowel and bladder segments are kept moist with protective plastic dressings as with bladder exstrophy (Gearhart and Jeffs, 1998). Presence of neurospinal abnormalities requires immediate neurosurgical evaluation. Consultations from social work, pediatric orthopedic surgery, and other disciplines should be obtained. Evaluation of the genitalia and gender assignment should be made by a gender assignment team, including a pediatric urologist, pediatric surgeon, pediatrician, pediatric endocrinologist, and child psychologist or psychiatrist. Gender assignment decisions should be made in conjunction with appropriate parental counseling and

Figure 139-32. A 46,XY child with cloacal exstrophy with a dominant right hemiphallus. This child underwent reconstruction and was reared as male.

involvement. In a large medical center with experience in dealing with complex malformations, these multiple consultations should be done in a short period of time. If there are medical concerns or the bladder segments are too small for closure, delayed closure after initial intestinal diversion is appropriate (Mathews et al, 1998).

Gender Assignment

Because of the significant separation of the corpora of the penis and scrotum and the reduction in corporeal size noted in boys with cloacal exstrophy, early reports had recommended universal gender reassignment of boys (46,XY) with cloacal exstrophy to functional females (Tank and Lindenaur, 1970). To this end, bilateral orchiectomy was combined with phallic reconstruction as a functional clitoris and early or delayed vaginoplasty. Reiner and Gearhart (2004) have reported on 29 males with cloacal exstrophy who had gender reassignment to female. Psychosexual evaluation indicated that all of these patients had a marked male shift in psychosexual development despite having no pubertal hormonal surges. Mirheydar and colleagues (2009) reported a case of masculinization in a 46,XY gender-converted patient secondary to an ectopic testis. A comparison of patients with cloacal exstrophy and other cloacal anomalies at the Great Ormond Street Hospital for Sick Children, however, indicated no difference in social or behavioral competence or psychological problems. Gender assignment was not associated with childhood psychological, emotional, or behavioral problems (Baker Towell and Towell, 2003). Schober and coauthors (2002), reporting on 14 children who had undergone early gender reassignment, indicated that although patients had masculine childhood behavior, they had a feminine gender identity. Currently, however, most authors recommend assigning gender that is consistent with karyotypic makeup of the individual if at all possible (Fig. 139-32). A recent survey of pediatric urologists indicated that two thirds of respondents favored gender-congruent assignment (Diamond et al, 2006). This policy can be supported by a report indicating that the histology of the testis at birth is normal (Mathews et al, 1999a). Furthermore, with evolution of techniques for phallic reconstruction, a functional and cosmetically acceptable phallus can now be constructed (Husmann et al, 1989b; Massanyi et al, 2012).

Immediate Surgical Reconstruction

Cloacal exstrophy patients should undergo carefully planned and individualized reconstructions (Ricketts et al, 1991; Lund and Hendren, 1993; Mathews et al, 1998). For infants with spinal dysraphism and myelocystocele, neurosurgical consultation should be obtained and closure undertaken as soon as the infant's condition is medically stable. After closure of the myelocystocele, long-term

follow-up is mandatory to evaluate for subtle changes in the neurologic evaluation that could herald cord tethering. Symptomatic spinal cord tethering can be seen in up to 33% of children (McLaughlin et al, 1995). A more recent series evaluating neuro-orthopedic manifestations in cloacal exstrophy indicated that 57 of 68 children had spina bifida (Suson et al, 2010). Of 62 children who were of walking age, 37 were able to ambulate completely, 17 ambulated with devices, and 8 were wheelchair bound.

Neonatal omphalocele closure is recommended to prevent untimely rupture and is typically combined with intestinal diversion. Formerly, initial attempts focused on ileostomy with resection of the hindgut remnant. Since the recognition of the metabolic changes that occur in patients with ileostomy, an attempt is always made to use the hindgut remnant to provide additional length of bowel for fluid absorption (Husmann et al, 1989a; Mathews et al, 1998). Tubularization of the cecal plate with end colostomy has been shown to be beneficial in reducing the incidence of short gut syndrome (Sawaya et al, 2010). Enlargement of the hindgut remnant and increased water absorption have been noted in children who have had the hindgut remnant incorporated into construction of a fecal colostomy (Taghizadeh et al, 2009). The hindgut segment may be anastomosed in an isoperistaltic or retroperistaltic fashion to increase motility and generate formed stool. Children who have anal stenosis and not imperforate anus may have the capability for later continence and may be treated with a pull-through procedure (Ricketts et al, 1991). If the hindgut remnant is not used for bowel reconstruction, it should be left as a mucous fistula to be used for later bladder augmentation or vaginal reconstruction (Lund and Hendren, 1993; Mathews et al, 1998). If gastrointestinal reconstruction is combined with bladder closure, approximation of the pubis, usually with osteotomies, is beneficial in reconstruction of the pelvic ring and increases the potential for successful bladder and abdominal wall closure (Mathews et al, 1998). Some authors have suggested that gastrointestinal reconstruction after initial fecal diversion be delayed for 1 to 2 years of observation (Soffer et al, 2000). After this time, radiographic evaluation is performed to determine residual colonic length. If near-normal colonic length is noted, a pull-through procedure is performed. If there is short colon but the patient is able to make solid stool, the patient may still be a candidate for pull-through procedures. A number of patients who can make solid stool are now able to be managed with pull-through procedures in conjunction with bowel management strategies to help them stay clean (Levitt et al, 2008). Bowel-lengthening procedures have also been used to improve absorptive function and benefit nutritional outcomes (Figueroa-Colon et al, 1996). Children who are unable to make solid stool are typically managed with a permanent fecal stoma.

At the initial stage of omphalocele closure, if it is determined that bladder and abdominal wall closure may not be accomplished, the bladder halves are approximated in the midline without further dissection and the defect is converted to a bladder exstrophy (Ricketts et al, 1991; Mathews et al, 1998). This permits abdominal distention to allow enlargement of this bladder plate for later closure. If the hindgut segment is not used in the initial reconstruction of the bowel, it is left as a mucous fistula.

Urinary Reconstruction

Modern Staged Reconstruction

The staged management of the urinary tract follows that used for the management of bladder exstrophy (Gearhart and Jeffs, 1991b). Once the bladder halves have been approximated posteriorly, the lateral edges are separated from the abdominal wall and brought together in the midline. As in the patient with classic exstrophy, placement of the bladder and posterior urethra deep into the pelvis remains a key factor in the successful surgical reconstruction of the urinary tract. Use of an AlloDerm patch to reduce the incidence of erosion of the interpubic stitch and prevent penopubic fistulization has been shown to be beneficial (Henderson et al, 2010). Inguinal hernias that are noted should be repaired at the time of closure. In

genetic females and in genotypic male subjects undergoing gender reassignment, reconstruction should be performed to improve the appearance of the genitalia. Recent reports by [Thomas and colleagues \(2007\)](#) in a series using a staged approach found successful results in a series of seven patients, all with tethered cords.

Reconstruction of the external genitalia in the immediate postnatal period is performed to make the infant's appearance more congruent with the gender assigned. The psychiatric studies of children who have had gender assignment have fueled interest in male gender assignment if adequate unilateral or bilateral corporeal tissue is present ([Reiner, 2004](#)). Histologic studies indicate normal histology in the testes of male subjects who have had gender reassignment despite the presence of cryptorchidism ([Mathews et al, 1999a](#)). Past results of phallic reconstruction in male patients with limited penile tissue have been disappointing. Penile replacement with phalloplasty has now permitted successful reconstruction to be performed and allows most if not all genotypic males to be raised with a congruent sex ([Lumen et al, 2008](#)). Multiple flaps have been used successfully for phallic reconstruction ([Bluebond-Langner and Redett, 2012](#); [Massanyi et al, 2012](#)). If male-to-female reassignment is deemed necessary, initial female genital reconstruction should bring the phallic halves together in the midline as a clitoris.

However, in instances with adequate corporeal tissue, either unilaterally or bilaterally, epispiadias repair can be performed at around age 1 using the standards identified for the staged reconstruction. Vaginal reconstruction can be performed early in the genetic female patient. In gender-converted male patients who require reconstruction of a neovagina, delayed reconstruction is appropriate. Reconstruction may be performed by using a preserved hindgut segment or expanded perineal skin ([Belloli et al, 1997](#)). Long-term dilation of the neovagina may be required.

Pubic approximation permits abdominal wall closure and usually requires osteotomy and fixation with postoperative traction. External fixation and traction are typically maintained for 6 to 8 weeks to permit healing.

Role of Osteotomy

Infants who are medically stable may be considered for urinary tract reconstruction in the immediate postnatal period. **Osteotomy is indicated in all children with cloacal exstrophy at the time of bladder closure because of the wide diastasis that is invariably present** ([Mathews et al, 1998](#)). Osteotomy allows the pelvic ring, bladder, and abdominal wall to be closed without undue tension on the closure. Reduction in dehiscence and postoperative ventral hernias has been noted in patients treated with osteotomy. In a large series reported by [Ben-Chaim and associates \(1995c\)](#), significant complications occurred in 89% of patients who underwent closure of the cloacal exstrophy without osteotomy but in only 17% of patients who underwent osteotomy at the time of initial cloacal exstrophy closure. It is interesting to note that the patients who underwent osteotomy and those who did not were similar in terms of size of the omphalocele, presence of myelomeningocele, and time of primary closure. However, it is not surprising that osteotomy had no effect on eventual continence of patients with cloacal exstrophy.

Currently, combined bilateral anterior innominate and vertical iliac osteotomies are routinely used at our institution ([Silver et al, 1999](#)). This approach does not require the patient to be repositioned on the operating table before commencement of bladder and abdominal wall closure. In addition, this method obviates the use of a posterior approach and any complication of the procedure related to the spinal or back closure. In a series of five patients with extreme pubic diastasis greater than 10 cm, [Silver and colleagues \(1999\)](#) described initial pelvic osteotomy and gradual pelvic closure of the fixator for 1 to 2 weeks, followed by abdominal wall and bladder closure. Closure was successful in all patients without technical problems or complications. This technique of staged pelvic closure may provide reliable initial secondary repair in patients with cloacal exstrophy in whom one-stage pelvic closure is not feasible, even with pelvic osteotomy. An interpubic titanium bar has been

Figure 139-33. Pubic apposition using titanium plate in cloacal exstrophy with extreme preoperative diastasis (8 cm) now with complete pelvic reduction.

added to permit stabilization of the pubic approximation and maintain the reduction in diastasis ([Fig. 139-33](#)) ([Mathews et al, 2006](#)). Because of the possible asymmetry that can be noted in the pelvic bones, care must be used when performing osteotomies and fixation. In patients who have lower extremity abnormalities, providing postoperative traction can also be challenging.

Failure of urinary reconstruction in children with exstrophy can lead to lack of growth of the bladder and may require loss of the bladder template. Recently [Shah and colleagues \(2014\)](#) identified potential causes for failure of the urinary reconstruction in a large series of children with cloacal exstrophy undergoing reconstruction at a tertiary medical center. They compared 26 patients (6,XY males, 8,XX females, and 12,XY gender-converted females) in whom prior urinary reconstruction had failed and who had been referred for reconstruction, with 34 patients (17,XY males, 12,XX females, and 5,XY gender-converted females) who underwent successful primary closure, to identify potential risk factors for failure.

It is interesting to note that 77% of patients with failed procedures had undergone closure in the first week of life, compared with 26% of those having undergone successful closure. In addition, only 31% of patients in whom closure had failed had osteotomy, compared with 82% of those who had undergone successful closure. In the patients with failed closure, 76% were immobilized with spica casts or mummy wraps. Among those in whom closure was successful, 56% were immobilized using modified Buck traction and external fixation, and an additional 20% were immobilized using Bryant traction with or without external fixation. Intersymphyseal plates to prevent separation of the pubis were used in 30% of patients with successful closure and in 50% of patients with successful reclosure. Ninety-two percent of patients with successful reclosure had osteotomy. Use of a technique that staged the closure over a 2- to 3-week period after performance of the osteotomy by gradually cranking the fixator medially was also shown to be of benefit in providing a successful primary or secondary closure ([Mathews et al, 2006](#)).

Single-Stage Reconstruction

[Grady and Mitchell \(1999\)](#) have reported using a single-stage reconstruction in cloacal exstrophy—a procedure similar to that done for bladder exstrophy. Delay in urinary tract reconstruction has also been advised by these authors if there is a large omphalocele or other medical instability. In this situation, the conversion to a bladder exstrophy and subsequent reconstruction of the bladder

and penis as a single step is performed. Lee and colleagues (2006) presented a limited experience in seven children with cloacal exstrophy who underwent reconstruction performed using a single-stage approach. There was one mortality before reconstruction. Six children who underwent reconstruction had dry intervals before toilet training. Some patients have required bladder neck injection to enhance continence. One child is voiding spontaneously and one child has undergone augmentation cystoplasty.

Techniques to Create Urinary Continence

Urinary continence is possible in most children but usually requires bladder augmentation and the use of intermittent catheterization. Multiple series by Gearhart and Jeffs (1991b), Mitchell and associates (1990), and Hendren (1992) have shown the applicability of modern techniques for lower tract reconstruction to help these patients achieve urinary continence. Enhancement of bladder capacity may be performed using a hindgut segment, if available; ileum; or stomach. Continence appears to be more difficult to achieve in male patients who undergo gender reassignment, and a continent stoma may be most applicable in this special group of patients (Mathews et al, 1998). In genetic female patients, successful continence has been achieved after Young-Dees-Leadbetter bladder neck reconstruction, but the vast majority of patients have required intermittent catheterization (Husmann et al, 1999). Similar findings were reported in a series by Mitchell and associates (1990). Husmann and colleagues (1999) reported that the success rate of Young-Dees-Leadbetter bladder neck reconstruction in the cloacal exstrophy population was closely related to the presence of coexisting neurologic abnormalities.

Urinary continence can be achieved in these individuals in many ways. An orthotopic urethra can be constructed from local tissue, vagina, ileum, stomach, or ureter. A catheterizable stoma can be constructed from ileum when enough bowel is present and fluid loss is not a problem. The bladder may be augmented with unused hindgut, ileum, or stomach. However, surgery to provide a continent urinary reservoir should be delayed until a method of evacuation can be taught and the child is old enough to participate in self-care. The choice between a catheterizable urethra and an abdominal stoma depends on the adequacy of the urethra and bladder outlet, interest and dexterity of the child, and orthopedic status regarding the spine, hip joints, braces, and ambulation. A more recent evaluation of a large cohort of children with cloacal exstrophy (Suson et al, 2010), indicates that over 50% of children (35 of 61) were able to achieve continence, 30 of 35 using intermittent catheterization through a continent stoma and the rest voiding or catheterizing via the urethra. An innovative approach is required to find a suitable solution for each individual patient according to the patient's bladder size and function and mental, neurologic, and orthopedic status.

LONG-TERM ISSUES IN CLOACAL EXSTROPHY

Because survival has become almost universal, the focus has changed in cloacal exstrophy to improving QoL. Improvement in functional outcomes has become the mainstay of improving the QoL. It must be stressed that although broad management strategies can be suggested, the management of patients with cloacal exstrophy must be individualized to maximize functional outcomes.

The factor most likely to lead to long-term disability is the level of the neurologic defect. Early aggressive evaluation and management of the neurologic issues with long-term close follow-up to evaluate for signs of cord tethering are critical to make sure that function can be preserved (McLaughlin et al, 1995).

Further management is most determined by the degree of neurologic deficit. When neurologic issues are minimal or absent, bowel pull-through and voided continence would be ideal. Ricketts and associates (1991) have presented a continence score that can be used in this group of children. Using a six-point scoring system to determine bowel and bladder continence (6 = best; 0 = worst),

they evaluated 12 patients who had been managed over time. They had 7 patients with a continence score of 1 (colostomy and incontinent bladder) and only 1 patient who had a score of 5 (enema program and a continent bladder), attesting to the difficulties presented with surgical reconstruction.

Some children have required permanent ileostomy for management of their gut. Husmann and colleagues (1999) noted that patients undergoing permanent ileostomy, in comparison with terminal colostomy, had greater initial morbidity; however, bowel adaptation appeared to occur by age 3 years with resolution of the short gut syndrome in most. If patients with terminal ileostomy were aggressively managed with hyperalimentation, growth characteristics in the two groups were very similar. As noted earlier, bowel reconstructive techniques have permitted most children to avoid the long-term debility associated with short gut syndrome.

Attempts at phallic reconstruction in the past had minimal success because of the diminutive nature of the corpora in boys and the wide pubic separation. Modern reconstructive surgical techniques may allow some boys to have complete phallic reconstruction performed with forearm or other grafts. Fertility appears to be universally compromised in boys, but girls have normal fertility, and pregnancy has been reported. Girls have higher degrees of cervical prolapse when compared with their counterparts with bladder exstrophy.

Summary

Evolution in management of cloacal exstrophy has permitted near-universal survival with significant improvement in cosmetic and functional outcomes. Debate continues regarding the issue of gender reassignment, and long-term data are still accruing on the best strategy for management. Continence can be achieved with appropriate reconstruction and the use of intermittent catheterization. Despite the extensive malformations noted, many patients have gone on to live fruitful lives.

KEY POINTS: CLOACAL EXSTROPHY—PRIORITIES IN MANAGEMENT

- Medical stabilization
- Gender assignment
- Colonic functionalization
- Separation of bladder from the gastrointestinal tract
- Functional genital reconstruction

Genetics

Embryology

Clinical Features

Presentation

Evaluation and Management

Long-Term Outlook

Pruno-belly syndrome (PBS) represents a constellation of anomalies with variable degrees of severity. The three major findings are a deficiency of the abdominal musculature, bilateral intra-abdominal testes, and an anomalous urinary tract. The urinary tract is characterized by variable degrees of hydronephrosis, renal dysplasia, dilated tortuous ureters, an enlarged bladder, and a dilated prostatic urethra. Additional associated anomalies involve the respiratory tract, gastrointestinal tract, cardiac system, and musculoskeletal system. There is a broad spectrum of severity of the syndrome, with some children not surviving the newborn period and others being minimally affected. The single most important determinant of long-term survival is usually the severity of the urinary tract anomaly, in particular, the degree of renal dysplasia.

Frolich (1839) first described the characteristic abdominal wall, and the full triad of anomalies was described by Parker (1895). Osler's vivid description of the abdominal wall of an infant with the characteristic findings led to the term *prune-belly syndrome* (Osler, 1901). Other names that have been applied to this syndrome include *triad syndrome*, *Eagle-Barrett syndrome*, and *abdominal musculature syndrome* (Eagle and Barrett, 1950; Greskovich and Nyberg, 1988).

The incidence of PBS has been reported as 1 in 29,000 to 1 in 40,000 live births, similar to that of bladder exstrophy (Williams and Burkholder, 1967), with 95% occurring in males (Wheatley et al, 1996). Females with PBS exhibit the abdominal wall deficiency and urinary tract dysmorphism without any gonadal anomaly (Rabinowitz and Schillinger, 1977; Reinberg et al, 1991b). A higher incidence is noted in twins, blacks, and children born to younger mothers. In developed countries, the incidence appears to be declining because of prenatal diagnosis and a decision to terminate the pregnancy. In a review reported by Routh and coworkers (2010) of the Kids' Inpatient Database (United States based), which evaluated newborns with PBS during their initial hospitalization between 2000 and 2006, the weighted incidence estimate was 38 cases per 100,000 live births (Routh et al, 2010).

GENETICS

The high male-to-female ratio, occasional occurrence in male siblings and cousins, and increased occurrence in twins suggest a genetic basis for PBS. Yet most cases are sporadic and have a normal karyotype. One in 23 children with PBS is the product of a twin pregnancy (Ives, 1974). However, the majority of reported twins have been discordant for PBS, which is evidence against a genetic etiology. It has been suggested that the etiology in twins may be a result of an uneven distribution of mesenchymal tissue at a critical time of primitive streak development during the third week of

embryogenesis (Coplen et al, 1996). There is a reported association with Turner syndrome, monosomy 16, trisomy 13, and trisomy 18 (Amacker et al, 1986; Hoagland and Hutchins, 1987). A variety of inheritance patterns have been proposed including X-linked recessive (Frydman et al, 1993), a two-step autosomal dominant mutation (Riccardi and Grum, 1977), and polygenetic transmission (Garlinger and Ott, 1974; Lockhart et al, 1979; Adeyokunnu and Familusi, 1982). A report by Ramasamy and colleagues (2005) suggested a sex-influenced autosomal recessive mode of inheritance in familial PBS. The consensus, however, remains that an associated chromosomal abnormality is the exception rather than the rule because most have a normal karyotype. Other reports have noted an association between PBS and Beckwith-Wiedemann syndrome (Silengo et al, 2002; Sinico et al, 2004).

EMBRYOLOGY

Several theories about the embryogenesis of PBS have been proposed. However, because there is no experimental model that can be used to test these theories, the exact mechanism remains elusive. The four chief theories are as follows: (1) early in utero posterior urethral obstruction resulting in severe dilation of urinary tract and possible fetal ascites and oligohydramnios (Strumme, 1903; Pagon et al, 1979; Beasley et al, 1988; Wheatley et al, 1996); (2) primary defect in the lateral plate mesoderm, which is the precursor of the ureters, bladder, prostate, urethra, and gubernaculum (Ives, 1974; Gonzalez et al, 1990); (3) an intrinsic defect of the urinary tract leading to ureteral dilation and fetal ascites (Symonds and Driscoll, 1974; Monie and Monie, 1979; Smythe, 1981; Nakayama et al, 1984; Cazorla et al, 1997); and (4) a yolk sac defect (Stephens, 1983; Stephens and Gupta, 1994). None of these theories has universal acceptance, and there is some overlap among them.

CLINICAL FEATURES

Genitourinary Anomalies

Kidneys

A spectrum of renal abnormalities extends from normal renal parenchyma to dysplasia (Figs. 140-1 and 140-2). The more severely dysplastic kidneys are generally associated with bladder outlet obstruction in which there has not been decompression through a patent urachus (Potter, 1972). Dysplasia is present in 50% of cases; however, it may vary in degree and laterally (Rogers and Ostrow, 1973; Stephens, 1983). Renal dysplasia in PBS of the Potter type II and type IV varieties is seen. The Potter type II variety

with few nephrons and parenchymal disorganization is more indicative of a renal mesenchymal defect, whereas the Potter type IV with cortical and tubular cysts is associated with outlet obstruction (Wigger and Blanc, 1977).

The renal collecting system is characteristically dilated, often to a severe degree. The degree of dilation, however, does not correlate with the degree of renal dysplasia. Calyceal morphology may be well preserved, even in the presence of massively dilated ureters and renal pelves (Berdon et al, 1977). Some patients may present with one severely dysplastic or dilated kidney, with the contralateral having only mild abnormalities. Ureteropelvic junction obstruction can occur on a primary or secondary basis; however, nonobstructive hydronephrosis is the rule (Woodard and Parrott, 1978b). It is renal

infection rather than obstruction that poses the greatest risk to renal function.

Ureters

The ureters are typically dilated, tortuous, and redundant (Fig. 140-3). The proximal (upper) portions of the ureters are usually less abnormal than the distal segments, although massive dilation and stenosis can occur at all levels. It is noteworthy that in many patients the severity of the urinary tract abnormalities is not proportional to the flaccidity of the abdominal wall. Histologic sectioning demonstrates a lack of smooth muscle cells and an increase in fibrous connective tissue. Generally there are more normal-appearing smooth muscle cells in the proximal segments (Palmer and Tesluk, 1974; Stephens, 1983). This fact is critical when ureteral reconstruction is undertaken. The ratio of collagen to smooth muscle cells in prune-belly ureters has been noted as elevated, especially in refluxing ureters (Gearhart et al, 1995). A decreased number of thick and thin myofibrils noted on ultrastructural examination is thought to contribute to the poor peristalsis (Berdon et al, 1977; Stephens, 1983).

Vesicoureteral reflux (VUR) is present in 75% of children with PBS (Berdon et al, 1977; Fallat et al, 1989) (Fig. 140-4). Obstruction is not common but has been reported at both the ureteropelvic and ureterovesical junctions (Wigger and Blanc, 1977; Moerman et al, 1982; Manivel et al, 1989).

These large ureters may have ineffective peristalsis because of poor ureteral wall coaptation. The ureteral conduction wave reaches a reduced smooth muscle cell population of poor contractile potential related to reduced myofibrils, often separated by patches of collagen with a resulting bolus of urine reaching more dilated ureteral segments as it progresses toward the bladder (Woodard and Smith, 1998). This can be seen fluoroscopically as ineffective peristalsis, resulting in upper tract stasis, which may lead to infection (Nunn and Stephens, 1961; Williams and Burkholder, 1967).

Figure 140-2. Unilateral renal dysplasia with dilation and tortuosity of the ureter in a patient with prune-belly syndrome.

Figure 140-3. Excretory urogram (A to C) demonstrating the variability in the degree of hydro-ureteronephrosis in prune-belly syndrome. Note the preservation of calyceal architecture, despite severe ureteral dilation in C. D, Dilated tortuous refluxing ureters as seen on a voiding cystourethrogram.

Bladder

The bladder usually appears as massively enlarged with a pseudodiverticulum at the urachus (Fig. 140-5). The urachus is patent at birth in 25% to 30% of children (Lattimer, 1958; Wigger and Blanc, 1977; Stephens and Gupta, 1994). Despite being very thick, the bladder wall is smooth, unlike that seen in obstructed bladders. Histologically, the bladder has an increased ratio of collagen to muscle fibers in the absence of obstruction (Workman and Kogan, 1990). Smooth muscle hypertrophy can be seen, however, in the obstructed prune bladder (Perlmutter, 1976). The pelvic distribution of ganglion cells has been shown as normal (Nunn and

Stephens, 1961; Burke et al, 1969); however, a decrease in α_1 -adrenoceptor immunostaining intensity has been documented (Schneider-Monteiro et al, 2010). Stephens demonstrated that the trigone is splayed with the ureteric orifices displaced laterally and superiorly, possibly contributing to the high incidence of reflux (Williams and Burkholder, 1967).

On voiding, the bladder neck opens widely into a dilated prostatic urethra (see Fig. 140-5). Urodynamic assessment generally shows normal compliance; however, there is a delayed first sensation to void and there is a large capacity (Snyder et al, 1976). The ability to empty the bladder is variable, with some emptying well and others carrying a significant postvoid residual. This is thought

Figure 140-4. Voiding cystourethrogram of a child with prune-belly syndrome demonstrating urethral atresia, urachal diverticulum, and vesicoureteral reflux (VUR).

Figure 140-5. Voiding cystourethrogram of a child with prune-belly syndrome demonstrating prostatic urethral enlargement related to a hypoplastic prostate and also demonstrating a urachal diverticulum. VUR, vesicoureteral reflux.

to be a result of a relative outlet obstruction and the ability of the bladder to generate sufficient pressure with a detrusor contraction. When the relative outflow resistance prevents effective bladder emptying, the term *unbalanced voiding* is used (Snyder et al, 1976; Kinahan et al, 1992). Despite these limitations, about 50% of prune-belly patients void spontaneously with normal voiding pressures, normal flow rates, and low postvoid residuals (Nunn and Stephens, 1961; Kinahan et al, 1992). However, as Kinahan and colleagues (1992) demonstrated, deterioration of balanced voiding can occur, resulting in significant postvoid residuals and emphasizing the need for periodic assessment.

Prostate and Accessory Sex Organs

The dilation of the posterior urethra is caused by prostatic hypoplasia, probably related to abnormal mesenchymal-epithelial development (Stephens and Gupta, 1994). Histologically, there are few

prostatic cellular elements with a reduction of both epithelial and smooth muscle cells and an increase in connective tissue cells (Moerman et al, 1982; Popek et al, 1991; Stephens and Gupta, 1994). Various obstructive lesions of the distal posterior urethra have been described—urethral atresia, valves, urethral stenosis, urethral membrane, and urethral diverticulum—and are thought to occur in 20% of cases (Hoagland and Hutchins, 1987). Stephens (1983) described an angulation of the urethra during voiding, referred to as *type IV valves*, which results from a lack of prostatic parenchymal tissue. Prostatic hypoplasia, the etiology of which is controversial, is thought to be a factor in the ejaculatory failure of PBS patients (Volmar et al, 2001). The vas deferens and seminal vesicles are often atretic, although either may be dilated or thickened (Stephens and Gupta, 1994). The epididymis may be poorly attached to the testis, as is seen commonly in abdominal undescended testes. There may also be a lack of continuity between the efferent ductules and the rete testis. Ejaculation is usually in a retrograde fashion because of an incompetent bladder neck.

Anterior Urethra

Although the anterior urethra of the PBS child is usually normal, several anomalies of the anterior urethra have been reported, with the most common being urethral atresia or hypoplasia and megalourethra (Kroovand et al, 1982; Perrotin et al, 2001). Unless it is associated with a patent urachus, urethral atresia is often lethal (see Fig. 140-4). It has been postulated that urethral atresia or hypoplasia occur because the urethra is unused rather than malformed. Spontaneous bladder rupture with fistula formation has also been reported (Reinberg et al, 1993).

PBS is associated with two variations of megalourethra (Shrom et al, 1981; Mortensen et al, 1985). The fusiform type is a deficiency of the corpus cavernosum, as well as the spongiosum, and the scaphoid variety is a deficiency of the spongiosum only with preservation of the glans and corpora cavernosa (Fig. 140-6). With the scaphoid variety, the ventral urethra dilates with voiding, whereas with the fusiform variety the entire phallus dilates with voiding. The fusiform variety is thought to result from a mesenchymal deficiency of the urethral folds, whereas the scaphoid variety results from a mesenchymal deficiency of the urethral supportive tissues (Dorairajan, 1963). Megalourethra is more commonly seen in PBS than any other syndrome (Appel et al, 1986). Transient in utero obstruction of the junction between the glanular and penile urethra has been proposed as a cause of megalourethra.

Testes

Bilateral intra-abdominal testes lying over the iliac vessels and adjacent to the dilated ureters are the most typical findings. Although mechanical forces such as a distended bladder and intra-abdominal pressure have been implicated in maldescent of the testes (Kaplan et al, 1986; Hutson and Beasley, 1988), the fact that some patients with the typical urinary tract and abdominal musculature anomalies (termed *pseudoprune patients*) may have descended testes raises some doubt about the pure mechanical factors.

Pak and colleagues (1993) compared the histology of the testes in PBS patients with that of non-prune-belly intra-abdominal testes and that of age-matched control subjects. They found no difference in germ cell counts, Ad spermatogonia, and Leydig cells between PBS testes and non-PBS intra-abdominal testes. However, because germ cell counts in PBS patients younger than 1 year are similar to those of age-matched controls, the implication is that the environmental state of the abdomen is a major factor in their later spermatogenic potential (Nunn and Stephens, 1961; Coplen et al, 1996). This mirrors findings of Nunn and Stephens (1961) of normal germinal epithelium of fetal and newborn PBS testes. Alternatively, Orvis and colleagues (1988) noted decreased numbers of spermatogonia and Leydig cell hyperplasia in fetal PBS testes, implying an intrinsic testicular abnormality. Azoospermia was found in adult PBS patients, and no PBS patient has been reported as having fathered a child (Woodhouse and Snyder, 1985). The

Figure 140-6. Scaphoid megalourethra and prostatic urethral dilation.

infertility is thought to be caused by a combination of testicular histologic abnormalities, structural defects of the ducts, and prostatic abnormalities (Tayakkanonta, 1963). More recently, paternity with normal live births was documented in adult patients with classic PBS, achieved by sperm retrieval techniques and intracytoplasmic sperm injection (Kolettis et al, 1999; Fleming et al, 2013). Normal pregnancy with assisted vaginal delivery was also described in a female patient with the syndrome (Hillman et al, 2012).

Three cases of testis tumor have been reported (Woodhouse and Ransley, 1983; Sayre et al, 1986; Massad et al, 1991; Parra et al, 1991). Massad and colleagues (1991) described histologic testicular patterns similar to those in intratubular germ cell neoplasia in three infants. Although the risk of malignancy may be relatively low considering the lack of germinal epithelium (Uehling et al, 1984), it is clear that placement of the testis in the scrotum and long-term follow-up are necessary to reduce the risk of testicular malignancy and to enhance detection.

Extragenitourinary Abnormalities

Of all children with PBS, 75% have non-urinary tract abnormalities (Geary et al, 1986). After the obvious abdominal wall defect, the most common abnormalities are cardiac, pulmonary, and orthopedic (Table 140-1). In addition to these organ-specific morbidities, nearly 50% of children with PBS are born premature, which significantly contributes to comorbidities.

Abdominal Wall Defect

The most characteristic feature of PBS in newborns is the appearance of the abdominal wall (Fig. 140-7). Although in some cases the musculature of the abdominal wall may be totally absent (Manivel et al, 1989), most commonly there is uneven involvement, with the medial and inferior musculature typically most deficient (Mininberg et al, 1973; Randolph, 1977). The appearance at birth is that of wrinkled, redundant skin with an abdomen that bulges in the flanks. One may be able to discern intra-abdominal organs through the thinned abdominal wall. The most severely affected areas may have skin, subcutaneous fat, and a single fibrous layer on the peritoneum (Mininberg et al, 1973; Baird and Sadovnick, 1987). Randolph conducted electromyographic mapping and demonstrated that the inferior and medial segments are the most consistently affected (Randolph et al, 1981a). Electron microscopy has demonstrated a nonspecific pattern of myofilament disarray, Z-line disorganization, and mitochondrial proliferation (Afifi et al, 1972; Randolph et al, 1981b; Woodard and Smith, 1998). The fact that normal spinal anterior horn cells have

been shown rules out a neuropathic etiology for the muscular deficiency (Nunn and Stephens, 1961). The muscular deficiency, however, is typically inconsistent and patchy and, as mentioned earlier, may be disproportional to the abnormalities of the urinary tract.

As the child grows older, the abdomen becomes less wrinkled and takes on more of a pot-bellied appearance (Fig. 140-8). Gait is usually not affected, although it may be delayed, and the children tend to roll to their sides and use their arms to sit from a supine position. The poor support of the lower chest wall results in flaring of the costal margin (Woodard and Smith, 1998). These children are more vulnerable to respiratory illness because their cough effectiveness is compromised. In spite of these abdominal wall issues, Woodard and Smith (1998) reported good wound healing without a tendency toward infections or incisional hernias.

Figure 140-7. The variability of the abdominal wall defect in patients with prune-belly syndrome.

Cardiac Anomalies

Cardiac anomalies such as patent ductus arteriosus, atrial septal defect, ventricular septal defect, and tetralogy of Fallot occur in 10% of children with PBS (Adebonojo, 1973). Cardiac abnormalities at birth may take precedence over urologic issues.

Pulmonary

Pulmonary difficulties can be observed at any age in patients with PBS. Pulmonary hypoplasia can result from severe oligohydramnios related to renal dysplasia or severe bladder outlet obstruction and may result in newborn demise. In addition, pneumothorax and pneumomediastinum can be seen with or without pulmonary hypoplasia (Skooog, 1992). Significant pulmonary difficulties have been reported in 55% of PBS survivors (Geary et al, 1986; Routh et al, 2010). In nearly half of PBS newborns, intubation and

mechanical ventilatory support will be required with its attendant morbidities (Routh et al, 2010).

The lack of ability to generate significant intra-abdominal pressure may contribute to pneumonia and lobar atelectasis (Alford et al, 1978; Ewig et al, 1996). Acute respiratory illnesses or an anesthetic procedure can easily lead to respiratory insufficiency in the PBS patient, who may have underlying chronic bronchitis from repeated respiratory illnesses. Many patients demonstrate significant restrictive lung disease secondary to musculoskeletal abnormalities such as scoliosis, rib cage abnormalities, and compromised abdominal musculature (Coplen et al, 1996).

Gastrointestinal Abnormalities

In at least 30% of cases, gastrointestinal anomalies are observed. The majority of the anomalies result from incomplete rotation of the midgut, giving way to a wide mesentery, which results in

increased bowel mobility with intestinal malrotation, volvulus, atresias, and stenosis (Silverman and Huang, 1950; Wright et al, 1986). Splenic torsion related to abnormal mesenteric fixation has also been reported (Heydenrych and Du Toit, 1978; Teramoto et al, 1981; Tran et al, 2013). Omphalocele, gastroschisis, and anorectal abnormalities have been reported (Petersen et al, 1972; Morgan et al, 1978; Wilbert et al, 1978; Short et al, 1985; Walker et al, 1987). With a limited ability to generate intra-abdominal pressure, constipation becomes a lifelong problem and leads to acquired megacolon (Woodard and Smith, 1998).

Figure 140-8. Older child with prune-belly syndrome, showing the absence of wrinkling, the “potbelly” appearance, and the consequent deformity of the lower ribs.

Orthopedic

Orthopedic abnormalities, ranging in incidence from 30% to 45%, are second in frequency to those of the genitourinary tract and abdominal wall. Many of these abnormalities result from the compressive effects of oligohydramnios. Some consider the musculoskeletal defects to result from the abnormal mesenchymal development at 6 weeks of gestation (Loder et al, 1992). Green and colleagues (1993), however, pointed out that because many of the deformities are unilateral, oligohydramnios is the most likely etiology. Dimpling of the lateral aspect of the knees is a common finding in oligohydramnios. Oligohydramnios may also result in talipes equinovarus (26%), hip dysplasia (5%), and congenital scoliosis (4%) (Woodard and Smith, 1998). It has been proposed that a distended bladder that may impinge on the external iliac vessels may compromise the blood supply to the lower extremities, and in severely affected cases it may result in lower extremity hypoplasia, absence, or amputation (Smith, 1913; Green et al, 1993).

Oral. There are reports on oral manifestations of the syndrome, including dental and bone abnormalities (Basso et al, 2012; Pessoa and Galvão, 2013).

KEY POINTS: CLINICAL FEATURES

- Hydroureteronephrosis is often present to a severe degree; however, the calyceal morphology may be well preserved.
- The proximal portion of the ureters has more normal muscle than the distal portions.
- The bladder is large with a pseudodiverticulum at the urachus and a wide bladder neck opening into a dilated prostatic urethra.

PRESENTATION

Prenatal Diagnosis and Management

Prenatal ultrasonography has played a major role in the identification of congenital genitourinary abnormalities. Fetal hydronephrosis can be diagnosed accurately in the second trimester and is present in approximately 1% of all pregnancies. However, the etiology of the hydronephrosis cannot be accurately determined in all cases. Elder (1990) estimated that the accuracy of determining the etiology of fetal hydronephrosis varies from 30% to 85%.

In particular, PBS presents prenatally with findings similar to those of other causes of bladder outlet obstruction (Fig. 140-9), as in posterior urethral valves, or megacystis megaureter syndrome (Kramer, 1983). Although an accurate diagnosis of PBS has been made as early as 11 to 14 weeks of gestation (Shimizu

et al, 1992; Yamamoto et al, 2001) (Fig. 140-10), the classic findings of hydronephrosis, a distended bladder, and an irregular abdominal circumference are not consistently seen at 30 weeks (Okulski, 1977; Bovicelli et al, 1980; Christopher et al, 1982; Shih et al, 1982). Early fetal ascites has been suggested to correlate with PBS (Scarborough et al, 1988). It is imperative to remember that the majority of patients with PBS do not experience demonstrable urinary obstruction and that the degree of hydronephrosis does not correlate with the postnatal renal function (Gadziala et al, 1982).

Whereas some have recommended in utero intervention for relief of urinary tract dilation and oligohydramnios (Gadziala et al, 1982; Glazer et al, 1982; Nakayama et al, 1984; Scarborough et al, 1988; Estes and Harrison, 1993; Leeners et al, 2000), others have recommended termination of pregnancy (Pescia et al, 1982). It is difficult to justify the advocacy of pregnancy termination in light of our inability to diagnose precisely the etiology of prenatal hydronephrosis and the inability to predict postnatal renal function on the basis of the degree of urinary tract dilation, except in rare cases of early and severe oligohydramnios. Prenatal intervention has been applied to PBS with no proven benefit in terms of postnatal renal function (Elder et al, 1987; Sholder et al, 1988; Freedman et al, 1999; Biard et al, 2005; Blaicher et al, 2005). The only circumstances in which prenatal intervention may be justified are the rare situations of urethral atresia with progressive oligohydramnios (Steinhardt et al, 1990; Reinberg et al, 1993; Perez-Brayfield et al, 2001) or cases in which decompression of the urinary tract is necessary to prevent dystocia (Gadziala et al, 1982).

Neonatal Presentation

The way that the abdominal wall appears immediately suggests a diagnosis of PBS (see Fig. 140-7) whether or not the diagnosis was suspected prenatally. It should be remembered that other associated abnormalities, such as cardiac or pulmonary, should often take precedence over the urinary tract, because, in the absence of true bladder outlet obstruction as seen with urethral atresia, the hydronephrosis is not life threatening.

Spectrum of Disease

With the number of variable anomalies present in PBS, it is understandable that there is a wide spectrum of clinical presentations. As described by Woodard (1985), there are three major categories of presentation in the neonatal period (Table 140-2).

TABLE 140-2 Spectrum of Prune-Belly Syndrome

CATEGORY	CHARACTERISTICS
I	Renal dysplasia Oligohydramnios Pulmonary hypoplasia Potter features Urethral atresia
II	Full triad features Minimal or unilateral renal dysplasia No pulmonary hypoplasia May progress to renal failure
III	Incomplete or mild triad features Mild to moderate uropathy No renal dysplasia Stable renal function No pulmonary hypoplasia

Category I consists of neonates who have experienced marked oligohydramnios as a result of renal dysplasia or severe bladder outlet obstruction with resultant pulmonary hypoplasia and skeletal abnormalities. Most infants with urethral atresia fall into this category. The exceptions to this are patients with urethral atresia and a patent urachus (Rogers and Ostrow, 1973). Those in this category who are not stillborn commonly succumb within a few days of life to pulmonary hypoplasia or later to renal failure. Approximately 20% of newborns with PBS die in the perinatal period (Woodard and Parrott, 1978b; Burbige et al, 1987; Fallat et al, 1989). It would be unusual for any urologic intervention in this category of patients to alter the course of events. Simple catheter drainage is all that is justifiable.

Category II demonstrates the full spectrum of the disorder with moderate or unilateral renal insufficiency and moderate to severe hydronephrosis. Pulmonary hypoplasia is not a prominent feature of this group of patients. The clinical course is that of stabilization of renal function at or somewhat below normal or progressive azotemia. Significant controversy regarding management exists in this group of patients (Waldbaum and Marshall, 1970; Randolph, 1977; Woodard and Parrott, 1978b).

Category III consists of patients with mild features of the triad or incomplete forms of PBS. This category comprises the majority of PBS patients in whom hydronephrosis is present to some degree but renal function is well maintained (Woodhouse et al, 1982; Woodard, 1998). There is no evidence of pulmonary insufficiency. There is little controversy that urologic intervention in the group is reserved for patients who demonstrate repeated urinary tract infections, probably related to urinary stasis, VUR, or the development of upper tract deterioration (Woodard and Smith, 1998). As previously noted, there is poor correlation between the extent of abdominal wall deficit and the degree of hydronephrosis or renal dysplasia, or both. This is also apparent in other variants of the syndrome. Some children have markedly dilated urinary tracts with minimal or no dysplasia and therefore normal renal function. Therefore the appearance of the abdominal wall or the degree of hydronephrosis may have little bearing on the long-term prognosis of children with PBS.

Incomplete Syndrome

These are male patients who may not have all the features of the triad syndrome but share other features. Most typically, these incomplete forms of the syndrome would lack the typical abdominal wall features but have the common uropathy and cryptorchidism. Many of these patients may eventually experience renal failure and they therefore require close observation, monitoring, and selective intervention. Bellah and colleagues (1996) reported a relatively high (8 of 15) tendency to progressive renal failure in a population of pseudoprune patients. This may be partially attributed to a delay in diagnosis in the absence of the obvious abdominal musculature deficiency and therefore a tendency to present with recurring urinary tract infections (Bellah et al, 1996).

Adult Presentation

Patients with incomplete forms of PBS and those specifically who lack the abdominal wall features may present as late as adulthood with symptoms of renal failure and hypertension (Lee, 1977; Kerbl and Pauer, 1993). Although there have been isolated reports of adults with no history of urinary tract infections, most others who present in adulthood eventually develop urinary tract infections from the chronic urinary stasis associated with the syndrome (Culp and Flocks, 1954).

Female Syndrome

Five percent of PBS patients are female, most of whom have the abdominal wall deficiency and the abnormal urinary tract (Reinberg et al, 1991b). Rabinowitz and Schillinger (1977) reported female patients with the typical abdominal wall deficit and a normal urinary tract. In the series of Reinberg and colleagues (1991b), bladder outlet obstruction was commonly seen along with a 40% occurrence of anorectal anomalies similar to the statistics for the male; 40% did not survive the newborn period.

EVALUATION AND MANAGEMENT

The initial evaluation of the newborn with PBS requires a team consisting of a neonatologist, a nephrologist, and a urologist. As dictated, other specialists may be indicated, particularly a cardiologist. Early orthopedic evaluation is also warranted. The major initial concern is that of management of cardiac and respiratory issues. An immediate chest radiograph is necessary to exclude commonly associated pulmonary abnormalities such as pneumothorax, pneumomediastinum, and pulmonary hypoplasia that is commonly a result of oligohydramnios (Perlman and Levin, 1974). Early urologic intervention is indicated only for neonates with evidence of bladder outlet obstruction, in whom a percutaneous suprapubic tube can be inserted while the newborn is in the neonatal intensive care unit.

Initial evaluation of renal function and the urinary tract status is important but must be tempered by transitional neonatal physiology. Although an initial creatinine level is important in establishing a baseline, it may be more reflective of the mother's renal function, and therefore the trend in creatinine levels throughout the course of the early postnatal days or weeks is much more predictive of long-term renal function.

KEY POINTS: INITIAL MANAGEMENT

- A neonatology, nephrology, and urology team is necessary, including members from other specialties such as cardiology.
- A voiding cystourethrogram (VCUG) is indicated in the neonatal period, only after antibiotic prophylaxis, especially if there remains renal insufficiency or evidence of bladder outlet obstruction.
- A chest radiograph to evaluate for pneumothorax, pneumomediastinum, and pulmonary hypoplasia is necessary.
- Baseline assessment of renal function should include renal and bladder ultrasonography, blood urea nitrogen (BUN), creatinine, and electrolytes.
- Circumcision is advisable in the absence of a structural penile abnormality.
- Early intervention is indicated for evidence of bladder outlet obstruction and preferably with a percutaneous suprapubic tube.

Serum, BUN, and electrolytes are necessary to assess for the potential systemic acidosis and electrolyte imbalances that may be seen in renal insufficiency. It has been shown in multiple reports that a baseline creatinine level less than 0.7 mg/dL is predictive of adequate renal function through childhood, in the absence of repeated insults from pyelonephritis (Geary et al, 1986; Reinberg et al, 1991a; Noh et al, 1999).

Early renal and bladder ultrasonography, after the newborn is stabilized, is necessary to assess the renal parenchyma for its thickness, density, and presence or absence of cortical cysts and degree of urinary tract dilation (see Fig. 140-1).

Avoidance of urinary tract infection is essential in light of the urinary stasis and often compromised baseline renal function. Circumcision is advisable in the absence of a structural penile abnormality to reduce the risk of infant urinary tract infections. Similarly, prophylactic antibiotic therapy is recommended, especially before urinary tract instrumentation, including the initial VCUG. Although instrumentation without a defined purpose, which may alter management, should be avoided, a VCUG to assess the bladder outlet and bladder emptying ability, especially in the presence of renal insufficiency, is warranted (Woodard and Smith, 1998). The VCUG is necessary in neonates with renal insufficiency to rule out as the etiology bladder outlet obstruction versus urinary stagnation. In up to 70% of children with PBS, VUR is diagnosed (Berdon et al, 1977; Fallat et al, 1989). Any instrumentation should be performed with strict attention to a sterile technique to reduce the risk of inoculation of a static urinary system. One can avoid an early VCUG in the presence of normal renal function and evidence of adequate bladder drainage per urethra or per a patent urachus.

As noted, neonates can be categorized based on their spectrum of disease (see Table 140-1). There is little disagreement on the management of category I PBS patients. There is no evidence that anything beyond supportive care is justifiable; in particular, intervention in the urinary tract is not indicated beyond simple bladder drainage because the results of these interventions cannot be altered (Woodard and Smith, 1998).

At the other end of the spectrum, category III patients rarely require early urologic intervention for the urinary tract because they are in a balanced state of hydronephrosis with good, if not normal, renal function. Children in this category require regular monitoring

of urinary tract dilation (ultrasonography) and renal function (serum creatinine), as well as urinary tract infection. However, their cryptorchidism requires correction during the first year of life. Some of these patients have persistent vesicoureteral reflux that may require surgical treatment on midterm to long-term follow-up, if symptomatic. Others will also benefit from abdominoplasty, as they may have significant flaccidity that persists or worsens during childhood.

Category II patients require individualization of evaluation and management based on the fact that within this category there are variable degrees of severity of each facet of PBS. There is, however, much controversy regarding their management. Evaluation of renal function, renal drainage, or both, is required in those with renal insufficiency. Excretory urography, although providing dramatic images of the urinary tract (see Fig. 140-3), does not provide sufficient information on comparative function. Renal parenchymal function is best assessed by a technetium-99m (^{99m}Tc) dimercaptosuccinic acid renal scan at 4 to 6 weeks of age to prevent difficulties in interpretation related to transitional neonatal physiology. Renal outflow obstruction is best assessed by ^{99m}Tc mercaptoacetyltriglycine, which also provides an assessment of comparative renal function with massive hydronephrosis and resultant stasis. In the presence of poor renal function, assessment of renal outflow obstruction by nuclear scan techniques may be limited; therefore selective use of the Whitaker antegrade perfusion test may help.

Controversies in Management of Category II Prune-Belly Syndrome

Aggressive surgical intervention was initially derived from early observations of the poor prognosis for category II infants as a group. Compilation of the cases reported in the literature between 1950 and 1970 by Waldbaum and Marshall (1970) showed that 86% of the 56 accurately traceable patients had died, with or without surgical intervention. The obvious implication was that a more aggressive approach was necessary to improve the fate of the infant with PBS. With the recognition that infection and progressive renal insufficiency are the factors that most often pose the greatest threat to quality of life and survival, surgical reconstruction to normalize the anatomy and function of the genitourinary tract was advocated. Early retailoring of the urinary system to reduce stasis and to eliminate reflux or obstruction has included ureteral shortening, infolding, and vesicoureteral reimplantation and reduction cystoplasty. Although very rare, eventual dysplastic or hydronephrotic kidneys with severely reduced function may require removal if they are symptomatic. Reconstruction is best delayed until the child is at least 3 months of age to allow for pulmonary maturation. This approach has been successful in achieving anatomic and functional improvement as evidenced by stable radiographic studies, stable creatinine values, and a reduced occurrence of infection (Waldbaum and Marshall, 1970; Jeffs et al, 1977; Woodard and Parrott, 1978b; Randolph et al, 1981b). Early urinary tract reconstruction can be performed in conjunction with orchiopexy, abdominoplasty, and circumcision, without increasing the morbidity of the procedure. In one of our personal reconstructive experiences (E.T.D.), 34 patients who have undergone urinary tract reconstruction have maintained normal creatinine levels, whereas four demonstrated moderate to severe renal insufficiency and two required renal transplantation, in a follow-up ranging from 1 to 27 years.

An alternative approach to limited surgical intervention has also been applied. Proponents advocate close surveillance with medical management of bacteriuria and surgical intervention only in patients with proven obstruction or intractable infection. Opinions vary about the management of VUR in the PBS population, although there is no reason to believe that reflux in this population is any less important, and correction of high-grade reflux seems prudent. Success with minimal surgical intervention has been reported (Woodhouse et al, 1979; Duckett et al, 1980; Tank and McCoy, 1983; McMullin et al, 1988). Woodhouse and colleagues (1979)

reviewed a series of patients with PBS who were managed conservatively. Nine of these 11 patients, who were monitored from infancy for periods of up to 24 years, remained well except for a few urinary tract infections. They were said to have normal voiding patterns and normal renal function. Thus patients in category III are candidates for this type of management.

The paucity of long-term data for category II patients, the probable variation in assignment of disease severity in treatment groups, and the variable natural history of the disease make comparisons of these retrospective studies difficult. Spontaneous improvement in ureteral appearance and function may occur with normal growth and elongation of the ureters (Duckett et al, 1980). Also, some patients with gross abnormalities of the urinary collecting system have survived for decades without medical attention (Asplund and Laska, 1975; Lee, 1977; Texter and Koontz, 1980). Yet progressive uropathy is also known to occur, and many patients with PBS ultimately require renal transplantation (Reinberg et al, 1989). Controversy will persist regarding category II patients until accurate application of a medical or surgical approach is possible on the basis of distinct clinical features. Dénes and colleagues (2004) emphasize the individualization of care in their 17-year experience with 32 patients.

Surgical Management of the Prune-Belly Syndrome Patient

Surgical management of children with PBS can be divided into three categories: urinary tract reconstruction, abdominal wall reconstruction, and orchidopexy. Urinary tract reconstruction is generally reserved for children with progressive or severe hydroureteronephrosis, recurrent upper tract infections, true obstructive uropathy, and progressive renal failure. Temporary urinary diversion also plays a role in the very young or the very ill child.

Supravesical Urinary Diversion

In certain instances the occurrence of repeated upper tract infections or deterioration of renal function dictates temporary urinary diversion. Although cutaneous vesicostomy usually provides adequate upper tract drainage and decompression, in rare instances more proximal diversion is indicated because of ureteropelvic or ureterovesical junction obstruction. Here a cutaneous pyeloplasty is advocated rather than proximal ureterostomy because it provides the best upper tract drainage and avoids sacrificing a normal proximal ureter that might be useful in later reconstruction.

Cutaneous Vesicostomy

Urinary diversion may be necessary as a temporary measure in children with acute renal failure, urinary sepsis, or bladder outlet obstruction from urethral atresia with limited patency of the urachus (Fig. 140-11) (Teramoto et al, 1981; Joseph, 1999). When temporary urinary diversion is indicated, a cutaneous vesicostomy is the procedure of choice. This is best performed by the Blocksom technique as described by Duckett (1974, 1986) and colleagues. If there is a large urachal diverticulum, it can be excised at that time. It is advisable to create a larger than normal stoma in the PBS patient because stenosis is common, probably because of the decreased intra-abdominal pressure (Snow and Duckett, 1987).

Internal Urethrotomy

The normal resistance of the urinary sphincter has been implicated in "unbalanced" urethrovesical function contributing to large postvoid residuals. Snyder and Cukier proposed lowering urethral resistance by internal urethrotomy to improve bladder emptying (Snyder et al, 1976; Cukier, 1977). In patients who were studied by urodynamic flow rate profilometry, improved flow rates with reduced residual urine and improvement in the radiographic appearance of the upper tracts were found (Snyder et al, 1976; Woodhouse et al, 1979). Although sustained long-term success has not been demonstrated, internal urethrotomy can be considered in PBS children

Figure 140-11. A, Prevesicostomy ultrasonography of the right kidney demonstrating massive hydronephrosis with echogenic parenchyma. B, Postvesicostomy ultrasonography demonstrating a decompressed kidney with echogenic parenchyma and cortical cysts. (Courtesy C. Peters.)

with high postvoid residuals, increasing hydroureteronephrosis, or VUR with recurrent upper tract infections. Williams (1979) advocated using an Otis urethrotome achieving a No. 24-Fr to 30-Fr caliber with one or two incisions made anteriorly or anterolaterally; however, direct visual urethrotomy would seem preferable and should be performed at the distal end of the prostatic urethra (Smith and Woodard, 2002). It is interesting to note that internal urethrotomy does not result in incontinence in this population.

Reduction Cystoplasty

In many PBS patients, poor bladder contractility leads to incomplete and infrequent emptying from the complicating urinary stasis and VUR issues. This leads to the concept of reducing the size of the bladder and remodeling it into a more spherical shape to direct better the contractible forces (Perlmutter, 1976). A variety of approaches have been proposed, from simple excision of the urachal diverticulum to the excision of redundant mucosa with the creation of an overlap between flaps to improve contractibility (Williams and Parker, 1974; Woodard and Trulock, 1986). With time, however, high bladder capacity and residual volumes seem to recur (Bukowski and Perlmutter, 1994). It seems therefore that reduction cystoplasty would be justified only to remove the larger urachal diverticulum or as part of a more extensive internal reconstruction. In some patients, intermittent catheterization through the urethra or through an appendicovesicostomy channel is likely to afford better long-term bladder emptying with reduction of residual urinary volumes until the patient is able to achieve better voiding pressures with age or as a result of abdominoplasty (Joseph, 1999).

Anterior Urethral Dilatation or Reconstruction

Urethral maldevelopment may be present as urethral atresia or hypoplasia (see Fig. 140-4). Patients with this abnormality may survive without any intervention, but they frequently require some form of treatment to improve bladder emptying. Passerini-Glazel and colleagues (1988) reported on progressive gentle urethral dilation with good success. This technique may be used in situ or through and through in cases in which a vesicostomy has been performed (Fig. 140-12). As reported by Reinberg and colleagues (1993), however, urethral dilation is not uniformly successful, and one may require a more formal urethroplasty with skin flaps, grafts, or both. Kajbafzadeh and colleagues (2010) reported significant improvement of the urethral caliber after one to three sessions of hydrodistention in patients with urethral hypoplasia.

Figure 140-12. Prune-belly syndrome patient with urethral atresia. Note vesicostomy and double-J stent through the urethra for progressive urethral dilation.

Megalourethra in PBS may be either fusiform or scaphoid (Appel et al, 1986). This is best approached with a circumferential subcoronal incision and penile degloving (Fig. 140-13A to F). The redundant urethra can be excised or infolded to provide support, and can be reconstructed over an appropriately sized catheter. Alternatively, some of the urethra can be used to reinforce the urethroplasty because in either form of megalourethra the spongiosum is deficient.

Ureteral Reconstruction

Ureteral remodeling remains controversial. It is best undertaken in children who demonstrated repeated nonsuppressible upper urinary tract infections or in those with progressive upper tract

Figure 140-13. Repair of megalourethra. A, The prepuce is reduced, and a circumcising incision is made, preserving a mucosal collar. B, With a catheter in place to assist with identification of the urethra, the penis is degloved along the subdartos plane. C, The involved segment of the urethra is opened longitudinally, and the redundant urethral wall is excised to allow tapering of the urethra over a catheter of appropriate size. D, The urethra is closed with absorbable running sutures and is bolstered with a second layer of sutures placed in an interrupted fashion if possible. E, The penile skin is brought forward, the excess foreskin is removed with a second circumferential incision, and the penile shaft skin is approximated to the mucocutaneous border (F).

deterioration. The goal of remodeling is to reduce urinary stasis. The key to success relies on a meticulous surgical technique and the preservation of the upper few centimeters of proximal ureter, which are less dilated, for reconstruction. Even then, tailoring or infolding of these segments may be necessary for adequate reimplantation into the abnormal bladder. This step can be difficult, in that the creation of a submucosal tunnel can be challenging (Woodard and Trulock, 1986).

In cases with associated secondary ureteropelvic junction obstruction, proximal ureterolysis without compromising ureteral vascularization may decompress the renal pelvis. In those with true mechanical obstruction, a nondismembered ureteropyelostomy between the dilated pelvis and a normal upper ureteral segment might normalize urinary drainage.

Woodard and his colleagues have demonstrated excellent success in this population when these procedures were performed in the neonatal period or in the older child (Woodard and Parrott, 1978b; Woodard and Zucker, 1990). They no longer, however, recommend such extensive reconstructive surgery before the age of 3 to 6

months. Fallat and colleagues (1989), as well as Dénes and colleagues (2004), have reported excellent results of extensive surgery including the reconstruction of the upper and lower urinary tracts, abdominoplasty, and orchiopexy in a single procedure in large groups of patients; both of these surgeons have more than 17 years' experience.

Orchidopexy

The timing of orchidopexy is dictated by our current understanding of the need for early treatment of the undescended testis in non-PBS patients along with individual PBS patients' needs for either temporary or reconstructive surgery. Although it is known that the fertility potential of the PBS patient is compromised, germ cells are present in the testes of infants with PBS. In addition, the prognosis for normal hormonal function at puberty is excellent. These factors, along with the potential risk for testicular carcinoma (Uehling et al, 1984; Massad et al, 1991), would justify early orchidopexy. Because the testes are uniformly located in the abdomen, most commonly

KEY POINTS: SURGICAL RECONSTRUCTION

- Upper urinary tract reconstruction is controversial but clearly indicated for evidence of declining renal function in the presence of hydronephrosis, recurrent upper tract infections, or progression of the hydronephrosis.
- Orchidopexy is best performed early in life because this affords the most likely prospect of a successful single-stage procedure.
- Abdominal wall reconstruction has demonstrated improved bladder emptying, a more effective cough, and improved defecation in addition to psychosocial benefits.
- Comprehensive surgery that includes all of the abovementioned points, as well as circumcision, are feasible in most patients.

on a broad mesorchium overlying the iliac vessels (Coplen et al, 1996), standard inguinal approaches are not usually successful in achieving a satisfactory scrotal position. Four alternative approaches may be considered.

Transabdominal Orchidopexy. Woodard, Parrott, and other researchers noted that if an orchidopexy is performed in the neonatal period and up to 6 months of age using a transabdominal approach, adequate spermatic vessel mobilization can usually be achieved for scrotal placement (Woodard and Parrott, 1978a, 1978b; Randolph et al, 1981a; Fallat et al, 1989). Transabdominal bilateral orchidopexy at about 6 months of age is currently considered the approach of choice (Fig. 140-14). This approach is often used in conjunction with other abdominal surgeries, such as vesicostomy, urinary tract reconstruction, or abdominal wall reconstruction. In the absence of the need for other abdominal surgeries, this procedure can be accomplished laparoscopically (Philip et al, 2011).

Figure 140-14. Intra-abdominal testes (arrows) overlying massively dilated ureters.

Spermatic Vessel Ligation. When successful transabdominal orchidopexy cannot be accomplished in the first few months of life, other options that may be considered include (1) Fowler-Stephens orchidopexy (Fowler and Stephens, 1959; Gibbons et al, 1979; Boddy et al, 1991; Kirsch et al, 1998), (2) staged Fowler-Stephens orchidopexy (Fig. 140-15) (Ransley et al, 1984; Bloom, 1991; Caldamone and Amaral, 1994; Docimo, 1995; Yu et al, 1995), and (3) microvascular autotransplantation (MacMahon et al, 1976; Wacksman et al, 1980; Boddy et al, 1991). A meta-analysis report by Docimo (1995) indicated comparative success rates of 67% and 77% for standard and staged Fowler-Stephens techniques, respectively. In a multi-institutional report of laparoscopic orchidopexy, Baker and colleagues (2001) noted a success rate of 81% for a standard Fowler-Stephens approach compared with 90% for a staged approach. In a long-term follow-up report, Patil and colleagues (2004) reported a satisfactory outcome for PBS with a one- or two-stage Fowler-Stephens orchidopexy. Some authors have recommended several technical adjustments during laparoscopic orchidopexy in children with PBS, particularly port placement, because there is little resistance to cannula placement in these children (Saxena and Brinkmann, 2007).

Reconstruction of the Abdominal Wall

Children with mild degrees of abdominal muscular deficiency may show improvement in the abdominal wall laxity as they mature. However, most others with moderate to severe degrees of abdominal wall laxity are left with a potentially psychologically crippling defect (Ehrlich et al, 1986; Parrott and Woodard, 1992). An elasticized corset can improve the external appearance when the wearer is fully clothed; however, the corset is inconvenient to use. There is general agreement about the cosmetic benefit of abdominal wall reconstruction. However, whether or not it improves bladder, bowel, and pulmonary function is controversial (Smith et al, 1998; Woodard, 1998). Smith and colleagues demonstrated improved bladder emptying following abdominal wall reconstruction; however, some of their reconstructed patients underwent concomitant urinary tract remodeling as well. Potential effects include a more effective cough and improvement in defecation. The timing of abdominal wall reconstruction should be dictated by the need for other surgical interventions, particularly if upper urinary tract remodeling is necessary. If upper tract remodeling is not anticipated, the abdominal wall can be addressed at any time and has been undertaken in patients as young as 6 months of age along with transabdominal orchidopexy (Smith and Woodard, 2002). If the procedure is done in infancy, however, one must be prepared to place the infant on a respirator postoperatively for a period of time. The following techniques have been described:

Figure 140-15. Operative photograph showing increased vascularity along vas deferens 4 months after first-stage Fowler-Stephens orchidopexy.

Randolph Technique

Randolph and colleagues (1981a) first popularized a technique for abdominal wall reconstruction based on electromyographic mapping, which indicated that the most severely affected area of the abdomen includes the infraumbilical regions, and the lateral and supraumbilical regions are generally least affected. This technique makes a transverse incision from the 12th rib to the pubic symphysis to the opposite 12th rib with a full-thickness removal of the skin, lower abdominal musculature, and peritoneum. The healthy fascia is then approximated to the anterior iliac spines, pubic tubercle, and inferior fascia. Although this technique is successful in establishing a waistline, lateral abdominal bulging often persists. Of the 16 patients reported, nine experienced excellent cosmetic results, and there was some residual protuberance in seven (Fallat et al, 1989).

Ehrlich Technique

The technique described by Ehrlich used a vertical midline incision and allowed the preservation of the umbilicus on a vascular pedicle

from the inferior epigastric artery (Ehrlich et al, 1986; Ehrlich and Lesavoy, 1993). The skin and subcutaneous tissues are elevated off the muscle and fascial layers, and an overlapping, vest-over-pants advancement of each side to the contralateral flank is performed, preserving the less affected lateral muscles and fascia. Excellent long-term follow-up of this technique has been reported (Lesavoy et al, 2012).

Monfort Technique

Monfort described a technique that is vertically oriented similar to that of Ehrlich's approach; however, an elliptically oriented incision is used to isolate the redundant skin (Monfort et al, 1991). The incision extends from the tip of the xiphoid to the pubis. A second incision is made around the umbilicus to preserve it in situ (Fig. 140-16A to J). The skin and subcutaneous tissue are dissected off the attenuated fascia and muscle with the dissection extending laterally to the anterior axillary line. Vertical fascial incisions are made lateral to the superior epigastric arteries, leaving a central fascial bridge. If intra-abdominal surgery is necessary, excellent exposure to the urinary tract or abdominal testes is afforded through these lateral fascial

Figure 140-16. Surgical technique for Monfort abdominoplasty and concomitant reconstruction of prune-belly uropathy. A, Delineation of redundancy by tenting up abdominal wall. B, Skin incisions are outlined with a separate circumscribing incision to isolate the umbilicus. C, Skin (epidermis and dermis only) is excised with electrocautery. D, Abdominal wall central plate is incised at the lateral border of the rectus muscle on either side, from the superior epigastric to the inferior epigastric vessels, creating a central musculofascial plate. E, Adequate exposure is provided for concomitant transperitoneal genitourinary procedures.

Continued

Figure 140-16, cont'd F, Only the more normal proximal ureter is preserved for vesicoureteral reimplantation, and the urachal diverticulum is excised. G, Transtrigonal ureteral reimplantation is performed with or without ureteral tapering as needed. The bladder is closed in two layers, and ureteral stents (not shown) and a cystostomy tube are used. H, Completion of abdominoplasty by scoring of the parietal peritoneum overlying the lateral abdominal wall musculature with electrocautery. I, The edges of the central plate are sutured to the lateral abdominal wall musculature along the scored line. J, Lateral flaps are brought together in the midline, with closed suction drains placed between the lateral flaps and the central plate. Skin is brought together in the midline, enveloping the previously isolated umbilicus. B, bladder; T, testis; U, ureter. (From Woodard JR, Perez LM. Prune-belly syndrome. In: Marshall FF, editor. Operative urology. Philadelphia: Saunders; 1996.)

incisions. The lateral fascial is then advanced over the central fascial bridge from both sides, alleviating the redundancy and increasing the thickness of the abdominal wall (Fig. 140-17).

A modification of the Ehrlich and Monfort technique was reported, in which, after the fusiform longitudinal resection of the midabdominal skin and subcutaneous tissue with preservation of the musculoaponeurotic fascia and umbilicus, one elliptical xiphopubic incision is made in the more flaccid side of the fascia, producing one wide and one narrow fascial flap, with the umbilicus being kept intact in the wide flap. Closure is made by suturing the wide flap laterally to the inner side of the narrow flap, followed by a vest-over-pants suture of this flap over the wide, now “inner” flap, with a buttonhole exposing the umbilicus, which is then fixed in place. After slight undermining of the skin edges, they are approximated and sutured with the incorporation of the umbilicus (Dénes et al, 2014) (Figs. 140-18, 140-19, and 140-20).

Furness and colleagues (1998) described a modified midline approach with less abdominal wall dissection, which avoids entering the peritoneum and which may be useful if intra-abdominal surgery is not planned. A modification of the Monfort technique uses laparoscopy to protect the abdominal contents (Franco, 2005).

LONG-TERM OUTLOOK

The nadir creatinine value during infancy has proven useful as a predictor of long-term renal function. If the nadir value is less than 0.7 mg/dL, renal function tends to be stable during childhood unless there is further renal compromise by pyelonephritis (Geary et al, 1986; Reinberg et al, 1991b; Noh et al, 1999). The importance of urinary tract monitoring by periodic cultures and prompt treatment of urinary tract infections cannot be overemphasized. Unfortunately the risk of infection is constant in the setting of urinary tract dilation and stasis. Up to 30% of patients, generally those with impaired renal function at initial evaluation, develop chronic renal failure during childhood or adolescence (Geary et al, 1986). Renal transplantation is necessary for these patients to ensure normal growth and development, and success with transplantation in PBS patients can be expected to equal that in other age-matched groups (Reinberg et al, 1989). Fusaro and colleagues (2004) have published a report of five boys with PBS who underwent renal transplantation. The 5-year graft survival rate was 66.7%, with all patients maintaining their native urinary tracts. Normal growth can be expected in most of the patients with normal renal function, although growth retardation in the absence of renal compromise

Figure 140-18. Prune-belly syndrome patient demonstrating preoperative appearance of abdominal wall (A), estimated extent of abdominal wall resection (B), and immediate postoperative appearance (C).

Figure 140-19. Abdominoplasty: elliptical excision of skin and subcutaneous tissue with preservation of umbilicus. An eccentric elliptical incision of the musculoaponeurotic fascia is made on the more flaccid side, creating broad and narrow flaps.

was observed in one third of patients in one series (Geary et al, 1986). A normal pattern of secondary sexual development can be expected (Woodhouse and Snyder, 1985). Although primary fertility is not expected in the PBS population, fertility with assisted reproductive techniques may be feasible for those experiencing successful early orchidopexy.

The overall outlook for the PBS patient, both for survival and for quality of care, has improved considerably, largely through advances in medical, surgical, and urodynamic management. However, despite these advances in care for children of PBS, there continues to be a high

perinatal mortality rate, largely resulting from associated prematurity and pulmonary complications (Routh et al, 2010). The key to management of the PBS patient is individualization of care, because some require major urologic reconstruction, and others require little if any reconstruction. Long-term surveillance of the urinary tract is essential because functional dynamics can change with time.

Description

Epidemiology

Pathophysiology of Posterior Urethral Valves

Diagnosis

Clinical Presentation and Initial Management

Surgical Intervention

Management of Vesicoureteral Reflux

Bladder Dysfunction and Valve Bladder Syndrome

Antenatal Management

Prognostic Indicators for Renal Function

Transplantation in Posterior Urethral Valve Patients

Quality of Life with Posterior Urethral Valves

Other Urethral Anomalies

Few afflictions of the newborn male share the irony of a relatively simple diagnosis and initial surgical intervention but significant long-term consequences characteristic of posterior urethral valves. As the most common cause of bladder outlet obstruction in infants, the presentation of posterior urethral valves is often antenatal, and pathognomonic findings on postnatal imaging confirm the diagnosis. Although an endoscopic ablation or urinary diversion will address the immediate uropathy, the embryologic insults to the bladder and kidneys manifest to varying extents, requiring that these boys remain under the extended care of urologists and nephrologists.

DESCRIPTION

A congenital obstruction of the posterior urethra ascribed to valve-like leaflets was recognized as early as 1769 by Morgagni, then confirmed by Langenbeck in 1802, both based on postmortem dissections. It was Hugh Hampton Young, however, who described the first endoscopic diagnosis of a urethral obstruction that was termed *posterior urethral valves* (Young et al, 1919). Despite the rudimentary nature of the early endoscopic instruments, Randall carried out the first endoscopic resection of valves in 1920, providing a description that remarkably encapsulates the visual findings of the posterior urethra even today:

The prostatic urethra is markedly dilated. The vesical neck raised and bladder orifice relaxed. Deep pittings penetrate down into either lateral wall of the prostatic urethra and at the extremity the verumontanum is seen a fine frenulum which extends distally for about 1 cm, and in dividing, forms what is apparently a definite valve on either side of the urethra, rising from the floor to each side wall. (Randall, 1921)

Young and colleagues (1919) were the first to propose a classification system for the lesion, based on an initial 12 patients, that remains a widely used contemporary nomenclature (Fig. 141-1). The type 1 lesion, pertinent to 95% of cases, is theorized as a hypertrophied variant of the inferior urethral crest formed by the insertion of the distal ends of the wolffian ducts into the anterolateral walls of the cloaca (Stephens, 1983). The urethral valves are actually leaflets that arise from the verumontanum, take an

anterior course, and then fuse in the midline just proximal to the external striated urethral sphincter. Some argue that the cleft seen in the midline—the “two forklike processes” as Young and coworkers described, or the leaflets fanning out from the verumontanum—are actually iatrogenic and created by retrograde instrumentation in the perinatal period (Dewan et al, 1994).

The type 2 valve of Young and colleagues, described as arising from the verumontanum and extending posteriorly and superiorly to the bladder neck, is not obstructing and has not been reported definitively since early reports. Stephens (1983) reported seeing no type 2 valves in 210 boys with posterior urethral valves examined with cystoscopy and suggested that the description was that of the secondary effects at the bladder neck of more distal obstruction.

The type 3 valve is similarly contentious as a diagnosis, but is most commonly described as an annular ring similar to that seen with a congenital urethral stricture. Young and colleagues (1919) described a complete obstruction “attached to the entire circumference of the urethra, there being a small opening in the center.” The embryologic origin for this variant affecting 5% to 10% of cases of outlet obstruction is thought to be a persistence of the urogenital membrane after the urorectal septum divides the cloacal membrane (Stephens et al, 2002).

A consensus view on the embryologic origins of posterior urethral valves remains elusive, though various mechanisms have been proposed. The earliest theory held that hypertrophy of the urethral mucosal folds was the cause of obstruction, which was furthered later to suggest cloacal remnants caused the appearance of valves after division by the urogenital membrane (Krishnan et al, 2006). Lowsley placed the origin of posterior urethral valves in an abnormal development of the wolffian and müllerian ducts based on an autopsy study in 1914 (Lowsley, 1914), but a more recent autopsy study corroborates the presence of a congenital obstructing posterior urethral membrane, consistent with a persistent oblique urogenital membrane that is punctured at the time of catheter or feeding tube placement by the medical practitioner in the immediate postpartum period (Dewan et al, 1994; Krishnan et al, 2006).

EPIDEMIOLOGY

Congenital anomalies of the urinary tract affect up to 1 in 500 pregnancies, and obstructive uropathy accounts for most of these cases

Figure 141-1. A, Young and colleagues' original figures from their 1919 article describing three types of posterior urethral valves. B, Illustration by William P. Didusch of the pathognomonic findings associated with posterior urethral valves: the thickened bladder with elevated bladder neck, the dilated prostatic urethra, and the valve leaflets commonly ascribed to type 1 valves. The ureters are shown to be dilated. (From Young HH, Frontz WA, Baldwin JC. Congenital obstruction of the posterior urethra. *J Urol* 1919;3:289.)

(Lissauer et al, 2007; Ruano, 2011). A large population-based registry study from the United Kingdom demonstrated that lower urinary tract obstruction (LUTO) has an incidence of 2.2 per 10,000 births, of which the most common pathology was posterior urethral valves (1.4 per 10,000 births), followed by urethral atresia and the prune-belly syndrome (Anumba et al, 2005). Since birth incidence requires the often inaccurate count of early spontaneous pregnancy loss, a later study following a similar cohort based in the West Midlands between 1995 and 2007 calculated a prevalence ratio of posterior urethral valves—number of affected births divided by the total number of live and stillbirths—of 2.10 per 10,000 births (Malin et al, 2012). This prevalence was also significantly higher in black and minority ethnic groups when compared with white Europeans.

A review of the Kids' Inpatient Database—a national database of inpatient pediatric hospitalizations in the United States—found 578 newborn males diagnosed with posterior urethral valves between 1997 and 2009. When divided by 10.0 million live male births in hospitals over that interval, this gave a weighted prevalence rate of 1.6 per 10,000 in-hospital live male births (Lloyd et al, 2013).

Considering that the United States alone may expect 300 to 500 new cases of infants with posterior urethral valves born annually—of which one third will go on to end-stage renal failure (Heikkilä et al, 2011)—the economic repercussions in terms of dialysis and renal transplantation arising from this congenital anomaly are enormous.

PATHOPHYSIOLOGY OF POSTERIOR URETHRAL VALVES

Although the initial treatment of posterior urethral valves—cystoscopy and valve ablation—is a relatively simple and reproducible procedure with adequate training, the bladder outlet obstruction during early fetal development creates downstream consequences that afflict an individual, often for a lifetime (Table 141-1). The long-term sequelae of valvular disease can be correlated to bladder dysfunction, renal dysplasia, polyuria, and multiple other anatomic and physiologic factors. Simply put, the bladder exposed to

KEY POINTS: DESCRIPTION AND EPIDEMIOLOGY

- Type 1 valves are the most common variant of posterior urethral valves, and appear as leaflets that arise from the verumontanum and fuse anteriorly just proximal to the external urethral sphincter.
- Type 3 valves present as a congenitally obstructing membrane that is likely perforated at the time of the initial post-natal catheterization.
- The incidence of posterior urethral valves is between 1.6 and 2.1 per 10,000 births.

developmental obstruction becomes hypertrophied, and empties well during the compensated phase. Over time, however, polyuria caused by renal dysplasia and continuing glomerular and tubular damage leaves the bladder without adequate periods of bladder emptying, leading to decompensation. This phase leads to increased bladder residuals that are causally linked to exacerbation of hydronephrosis and further renal damage.

Lower Urinary Tract

It cannot be overstated that the potential comorbidities arising from posterior urethral valves—renal dysfunction, urine reflux, worsening hydronephrosis—are due to bladder dysfunction. Mitchell (1982) coined the term *valve bladder syndrome* when he described 11 patients in whom bladder filling and emptying were noted to be intricately related to extent of renal pelvocaliectasis and overall renal function and dysfunction. This concept was subsequently illustrated as a “vicious cycle” leading to the valve bladder syndrome. Bladder hypertrophy secondary to the fetal obstruction results in higher voiding pressures that maintain complete bladder emptying in the compensated phase. The increased voiding pressures lead to gradual remodeling of the bladder wall, further increasing voiding pressures, and ultimately to higher postvoid residuals as emptying begins to fail. The rise in urine

TABLE 141-1 Damage Caused by Posterior Urethral Valves

ORGAN	EFFECT	NATURAL HISTORY
Lung	Pulmonary hypoplasia	May be fatal in newborns; if infant survives, there are few long-term problems
Kidney		
Glomerular injury		
Obstructive uropathy	Reversible renal insufficiency	Usually improves with initial treatment but can recur with bladder dysfunction
Dysplasia	Irreversible renal insufficiency	Permanent level of renal damage that limits growth; leads to progressive renal failure and hypertension
Tubular injury	Inability to limit sodium and water loss	Progressive with age; nephrogenic diabetes insipidus
Bladder	Poor sensation, hypercontractility, low compliance, and eventual myogenic failure all may contribute to incontinence and poor emptying	Bladder problems are lifelong and change with age
Ureters	Poor contractility and inability to coapt and transport urine	Most will improve initially, but most have chronic hydronephrosis

output with normal growth and development combined with the latent polyuria of existing renal dysplasia and increased glomerular pressure caused by poor bladder emptying conspire to increase urine volumes stored in the upper urinary tract. As this bolus of urine fills the bladder even as the bladder empties partially, a lack of extended periods of an empty, relaxed bladder pushes the compensated bladder toward decompensation. This, of course, leads to even greater postvoid residuals, overflow incontinence, and further renal damage (Close et al, 1997).

The storage and voiding of urine at high pressures has been simulated in fetal sheep and rabbit models in vitro to simulate and then investigate the cascade of events effectuating bladder smooth muscle alterations. Increased bladder dilation is seen following partial bladder outlet obstruction (Kirsch et al, 2003), and the dilated, poorly contracting bladders (simulating the decompensated bladder) lead to more upper tract dilation. Thus increased bladder dilation places the upper urinary tract at risk. This model and the work of other researchers confirmed that extracellular matrix elements line the detrusor smooth muscle cells of the bladder after obstruction—as noted in valve bladders (Workman and Kogan, 1990). Importantly, the pathologically significant elevated storage pressures must be distinguished from the neonatal and infantile elevated voiding pressures that are a normal feature of bladder development (Sillén et al, 1992).

There remains some controversy as to whether the changes in bladder morphology in the valve-affected bladder are reversible, as opposed to the phenotypic changes in neurogenic bladders that are more permanent (Keating, 1994; Hutcheson et al, 2004).

The deposition in the extracellular matrix causes altered contraction and passive relaxation of the bladder, which may cause multiple intracellular changes ranging from a reduction in detrusor blood flow causing ischemia to free radical toxicity. These changes alter the phenotype of detrusor muscle myosin bundles and actin-associated filaments (Ghafar et al, 2002; Shukla et al, 2004; Levin et al, 2005).

The valvular obstruction will also lead to marked dilation of the posterior urethra, hypertrophy of the bladder neck, and a flattening of the verumontanum with dilation of the ejaculatory ducts—the pathognomonic findings of this diagnosis on voiding cystourethrogram (Fig. 141-2 and Fig. 141-3). These changes seem to return to a more normal appearance following valve ablation as the offending distal obstruction is removed.

Upper Urinary Tract

A bladder exposed to posterior urethral valves undergoes a cascade of changes that alter the organ's normal function in storing and emptying urine. This bladder dysfunction manifests in varied ways

during infancy and later, and is discussed in a later section. What is apparent is that a sustained increase in intravesical storage pressures over prolonged time intervals transmits that pressure to the ureter, the renal pelvis, and ultimately the glomerular units—causing architectural and functional changes at each ascending structure (Koff et al, 2002). These architectural changes can be inferred clinically by the severe hydroureteronephrosis that is often seen in the setting of posterior urethral valves. Increased echogenicity, parenchymal thinning with cortical cysts, and lack of corticomedullary differentiation similarly imply significant renal dysplasia (Fig. 141-4A).

Ureteral dilation occurs as a direct transmission of pressure from the dysfunctional bladder, as well as the vesicoureteral reflux that is seen in up to 70% of patients with posterior urethral valves (Puri and Kumar, 1996; Sarhan et al, 2011). Polyuria caused by progressive renal damage and congenital renal dysplasia compound ureteral dilation as well (Smyth et al, 1991). The chronicity of ureteral dilation is classically believed to cause ureteral wall thickening, loss of peristalsis, and loss of mucosal coaptation, increasing the risk of urine stasis, infection, and increased pressures in the renal units (Fig. 141-4B) (Parkhouse et al, 1988; Glassberg, 2001).

The elevated renal pelvic pressures secondary to the bladder and ureteral pressure increases lead to significant alterations in renal morphology and function. The renal dysfunction seen in posterior urethral valves has two specific etiologies: (1) obstructive uropathy and (2) renal dysplasia.

Obstructive uropathy causing renal damage is a well-known phenomenon in various models. Fetal sheep ureteral obstruction models clearly demonstrate that, although hydronephrosis occurs rapidly after obstruction, irreversible dysplastic changes in the renal architecture are seen by term, and these changes were confirmed after outlet obstruction in the same model (Peters et al, 1992; Chevalier, 2004). Apoptosis and increased oxidative stress in mouse kidneys with ureteral obstruction are also seen in the face of bladder outlet obstruction (Kawada et al, 1999; Chevalier, 2004).

The increased pressure from obstruction damages luminal cells in the renal tubules and will also lead to poorly concentrated urine production (Li et al, 2004; Nguyen et al, 2005a). Obstruction may also affect urinary concentration by reducing blood flow to the medulla, causing a loss in the medullary concentration gradient that results in significant polyuria and even in the postobstructive diuresis seen after catheter placement in an infant with posterior urethral valves (Dinneen et al, 1995).

Although some debate whether the entirety of renal damage seen in posterior urethral valves is actually a secondary phenomenon resulting from obstruction, the observation that even early prenatal intervention does not necessarily forestall long-term

Figure 141-2. A, Voiding cystourethrogram image shows a bladder affected by multiple diverticuli and a dilated posterior urethra narrowing at the site of valvular obstruction. B, Cystoscopic image corresponding to the point of obstruction in A. Arrows indicate valve leaflet that would be fulgurated at the time of valve ablation. The urethral valves are seen as leaflets arising from the verumontanum and fusing in the midline, just proximal to the striated sphincter. The verumontanum is noted just proximal to the valve leaflets. C, Voiding cystourethrogram image shows an elevated bladder neck and dilated posterior urethral funneling to a point of obstructed flow. These are typical radiologic findings of posterior urethral valves. D, Cystoscopic image corresponding to point of obstruction in C. The concentric narrowing is classically associated with a type 3 valve but is also considered consistent with the congenital obstructing posterior urethral membrane that may have been perforated at the time of initial catheter placement.

renal disease posits that renal dysplasia may be concurrent with—rather than a consequence of—posterior urethral valves (Haecker et al, 2002). Others have demonstrated known primary dysplastic malformations of fetal cartilage tissue or dysplastic glomeruli and tubules in posterior urethral valves that affected renal tissue at the time of nephrectomy (Haecker et al, 2002).

A correlation between severe renal hypodysplasia and decreased activity of the renin-angiotensin system that modulates renal development has been noted in posterior urethral valves, as well as a decrease in the angiotensin receptor type 1 genetic polymorphisms (Peruzzi et al, 2005). Bajpai and associates (2005) found that plasma renin activity increases precede common clinical findings of renal damage such as rising serum creatinine, renal scars, and lowering glomerular filtration rate. Although angiotensin II contributes to renal damage by hemodynamic alterations in glomerular flow, it also induces profibrogenic actions and inflammation through the induction of transforming growth factor- β_1 and tumor necrosis

factor- α (Kagami et al, 1994; Furness et al, 1999; MacRae Dell et al, 2000). These cytokines are considered potential biomarkers that seem to decrease with improvement in renal function after valve ablation, whereas elevations imply worsening outcomes.

Institution of an angiotensin-converting enzyme inhibitor (ACEI) showed therapeutic potential in experimental studies by reducing fibrosis (Yu et al, 2004; Gagliardini and Benigni, 2006), and seemed to reduce expression of biomarkers such as transforming growth factor- β_1 and tumor necrosis factor- α in another clinical study, suggesting a potential role in selected children with posterior urethral valves (Mandelia et al, 2013). Further corroborating the hypothesis that renal damage in valves is due, in part, to dysplasia and not only obstruction is the finding that the *ACE1* gene is expressed significantly more, and the angiotensin receptor gene (*ATR*) less, in patients with posterior urethral valves compared to those with other dysplasias and controls (Peruzzi et al, 2005; Laksmi et al, 2010).

Figure 141-3. Cystoscopic views in an infant with posterior urethral valves of (A) elevated bladder neck and (B) trabeculations in affected bladder consistent with obstructive uropathy.

Figure 141-4. A, Left renal sonogram in a newborn with posterior urethral valves shows severe pelvocaliectasis with thinning of the parenchyma with increased echogenicity and loss of corticomedullary differentiation. B, Pelvic view of same patient, not yet catheterized, shows a distended bladder with dilation of bilateral distal ureters.

Vesicoureteral Reflux and Dysplasia

Hoover and Duckett (1982) observed that the high-grade vesicoureteral reflux seen in children with posterior urethral valves was usually into an ipsilateral poorly functioning renal unit, whereas the contralateral renal unit appeared to have preserved renal function (Fig. 141-5). They hypothesized that the reflux served as a pop-off mechanism in which the dysplastic kidney with reflux served as a pressure reservoir mitigating damage to the contralateral kidney, and coined the term *vesicoureteral reflux and dysplasia* (VURD). This relationship, in that original series, was found in 13% of patients with posterior urethral valves, and the theory that these children would have better long-term renal function as a result of the pop-off phenomenon was widely accepted.

Longer-term studies have confirmed, however, that the VURD syndrome does not improve renal prognosis. Fifteen years after the VURD syndrome was first described, Cuckow and colleagues (1997) found that, whereas 67% of patients affected by VURD during year 2 of life had a normal serum creatinine, only 30% of these children had normal values between ages 8 and 10 years. The glomerular filtration rate, importantly, was already abnormal in

75% of these same patients even in the first 2 years of life. Another observation that even the contralateral, nonrefluxing renal unit in VURD patients carries a high risk of congenital renal cortical damage—implying poorer long-term prognosis—means that VURD should never be allowed to create a false sense of security, and close follow-up as with any other cohort with posterior urethral valves is mandatory (Narasimhan et al, 2005).

KEY POINTS: PATHOPHYSIOLOGY OF POSTERIOR URETHRAL VALVES

- The renal dysfunction, vesicoureteral reflux, and voiding dysfunction seen in children with posterior urethral valves are mediated by a dysfunctional bladder.
- Renal impairment in posterior urethral valve patients is due to renal dysplasia and obstructive uropathy.
- The VURD syndrome confers no protective benefit on long-term renal prognosis.

Figure 141-5. Massive, dilating vesicoureteral reflux is seen on the left side on this voiding cystourethrogram and, in this case, is typically associated with a poorly functioning kidney on the ipsilateral side, referred to as the vesicoureteral reflux with dysplasia syndrome.

DIAGNOSIS

Ultrasonography

With widespread access to antenatal sonography, posterior urethral valves and other LUTOs such as urethral atresia or stenosis are increasingly detected during the fetal period. Posterior urethral valves are detected in approximately 1 in 1250 ultrasound screenings, accounting for 10% of significant antenatally detected genitourinary disease and afflicting one third of surviving infants with bilateral renal disease (Thomas and Gordon, 1989; Gunn et al, 1995). The pathognomonic ultrasound findings of a thickened, dilated bladder along with bilateral hydroureter and pelvocaliectasis do carry a high sensitivity (95%) and specificity (80%), and oligohydramnios and the dilated posterior urethra displaying the “keyhole sign” further corroborate the presence of LUTO (Figs. 141-6 and 141-7) (Peters, 1998; Robyr et al, 2005). Renal echogenicity will be increased in posterior urethral valves, and is a reliable indicator to infer renal damage as well.

However, although LUTO may be diagnosed prenatally, differentiating valves from urethral atresia or prune-belly syndrome, high-grade vesicoureteral reflux, or bilateral primary obstructing megaureters is much more problematic, reducing the accuracy of diagnosing posterior urethral valves with prenatal sonography alone to as low as 50% (Abbott et al, 1998). Still, the antenatal finding of a thickened, enlarged bladder and bilateral ureterectasis with pelvocaliectasis with or without oligohydramnios in a male infant requires an early postnatal sonogram and voiding cystourethrogram prior to the infant’s discharge from the postpartum unit (Lee et al, 2006; Herndon, 2012; St. Aubin et al, 2013).

Fetal magnetic resonance imaging (MRI) is an adjunct in prenatal diagnosis and increasingly available at major centers. As with ultrasonography, fetal MRI is used to distinguish the degree of obstruction based on urethral dilation, distended bladder size with thickening, and reduced amniotic fluid levels (Fig. 141-8). Lung hypoplasia and cystic changes in renal parenchyma are also appar-

Figure 141-6. Antenatal ultrasound examination demonstrates bilateral severe pelvocaliectasis with dilated bladder in fetus. LT, left kidney; RT, right kidney. (Courtesy Dr. Mark P. Johnson, Children’s Hospital of Philadelphia.)

Figure 141-7. Sonogram of fetal bladder shows a thickened bladder with dilated posterior urethra below, suggesting the “keyhole sign.” LT, left kidney; RT, right kidney; TRV, transverse. (Courtesy Dr. Mark P. Johnson, Children’s Hospital of Philadelphia.)

ent on MRI, though the rate of renal dysplasia does not necessarily correlate with micro- or macrocystic changes (Chauvin et al, 2012). One study of fetal MRI in early gestations showed that the modality altered the initial sonographic diagnosis in 30% of the cases (Poutamo et al, 2000). However, although MRI does provide added analysis of causes of obstruction in select cases, the utility of MRI is limited, as with sonography, in diagnosing the actual cause of LUTO (Miller et al, 2002).

Voiding Cystourethrogram

Voiding cystourethrogram (VCUG) remains the definitive radiologic study in confirming the diagnosis of posterior urethral valves. This study should be completed in the early postnatal period after renal and bladder sonography, and as soon as an infant with suspected prenatal findings of valves is hemodynamically stabilized and able to undergo the contrast study.

Figure 141-8. Fetal magnetic resonance imaging demonstrating lower urinary tract obstruction that was postnatally diagnosed as posterior urethral valves. A dilated bladder funneling to a visible posterior urethra (arrow) is seen on this T2 image.

The bladder often appears thickened and trabeculated with multiple diverticuli, mimicking the appearance of a neuropathic bladder. High-grade vesicoureteral reflux may be seen in approximately 50% of patients with valves at the time of diagnosis (Hassan et al, 2003). Images obtained during the voiding phase will show contrast traveling across a hypertrophied, elevated bladder neck and grossly dilated posterior urethra (Fig. 141-9). The urethra funnels abruptly at a transverse membrane, or cusp, representing the obstructing valve leaflets seen at cystoscopy. These are the pathognomonic signs for posterior urethral valves.

The study commences with the insertion of a 6- or 8-Fr feeding tube into the urethra. This tube may curl within the capacious posterior urethra or hypertrophied bladder neck, requiring the use of a coude catheter to advance into the bladder. Often a catheter may already be in place at the time of the study, and it is important that the catheter be withdrawn gradually distal to the posterior urethra during the voiding phase of the study to offer unobstructed views of that segment.

Radionuclide Renal Scan

The radionuclide renal scan offers quantification of differential renal function, and cortical deficits seen on the study may imply renal dysplasia when completed in the neonatal period. Mercaptoacetyl triglycine is a useful agent to evaluate renal functional contribution, though delayed emptying of nuclear tracer from the often dilated collecting systems should not be necessarily interpreted as ureterovesical junction obstruction requiring intervention. Placement of a urinary catheter is essential in a patient with vesicoureteral reflux to minimize error in the calculation of renal function.

Laboratory Evaluation

Laboratory evaluation of a newborn with a diagnosis of posterior urethral valves will, as with any newborn, reflect maternal values and must be interpreted with caution. After 48 hours, the maternal blood mediated through the placenta should clear, and the infant's baseline laboratory values may be monitored. The nadir creatinine

Figure 141-9. A, Voiding cystourethrogram image demonstrates a dysmorphic, elongated bladder with dilated posterior urethra and classic appearance of posterior urethral valves. B, Dilating vesico-ureteral reflux is seen bilaterally.

value at 1 year of age is considered an important diagnostic tool—and this value may be plotted to evaluate immediate response to treatment in the neonatal period. However, the serum creatinine plateau even in unaffected children may not be seen until days 65 to 220 of life (DeFoor et al, 2008, Boer et al, 2010).

CLINICAL PRESENTATION AND INITIAL MANAGEMENT

An infant affected by posterior urethral valves may be affected by serious comorbidities such as pulmonary hypoplasia and physical stigmata of oligohydramnios, including Potter facies, clubfeet and deformed hands, and poor abdominal muscle tone, and require intensive initial management. The infant may be noted to have difficulty with voiding, and the urinary stream may be weak or intermittent. A 5- or 7-Fr feeding tube, or similar caliber urinary catheter, should be inserted per urethra in an infant presenting to the

Figure 141-10. Plain radiograph of a 5-day-old infant with posterior urethral valves and bronchopulmonary dysplasia, requiring airway support, shows reduced lung volume and left upper and lower lobe atelectasis.

neonatal intensive care unit with a presumed diagnosis of LUTO. Catheter placement into the bladder may be impeded by the hypertrophied and often elevated bladder neck and curling of the catheter within the dilated posterior urethra. In such cases, a coude-tipped catheter or, alternatively, using a stylet to curl the tip of the feeding tube dorsally will facilitate bladder drainage. Minimizing any type of catheter balloon filling is important to prevent inducing bladder spasms in the small, hypertrophic bladder and potentially occluding the ureteric orifices (Jordan and Hoover, 1985). Placement of the catheter within the bladder may be confirmed by bladder sonography or, in some instances, a one-shot cystogram.

Pulmonary Hypoplasia

Whereas the focus in posterior urethral valves is too often on the lower urinary tract and kidneys, the most profound complication and cause of perinatal mortality in infants affected by severe LUTO remains pulmonary hypoplasia. The frequently cyanotic baby requires complex ventilatory support, and this is often the factor delaying definitive surgical intervention to address the valves. Pulmonary hypoplasia seen in the infant with a history of antenatally detected oligohydramnios may be the contributing factor to perinatal mortality in these children, requiring intensive and rapid supportive treatment (Pinar, 2004).

The association between posterior urethral valves, oligohydramnios, and pulmonary hypoplasia is recognized (Fig. 141-10), but the etiology of hypoplasia is unclear and likely multifactorial. It is recognized that the reduced expansion of alveoli because of hypoplasia adversely affects the development of the fetal pulmonary tree, which requires intraluminal pressure, volume, and flow while providing cellular signaling to the developing alveoli (Husain and Hessel, 1993; Laudy et al, 2002).

Although the concept that grossly hydronephrotic kidneys and a dilated bladder, combined with increased uterine pressure on the developing fetus resulting from oligohydramnios, reduce diaphragmatic expansion and affect lung volume and growth seems logical, it is an insufficient explanation for the clear correlation between pulmonary hypoplasia and oligohydramnios. Rather, the finding that abnormal pulmonary development commences in early embryogenesis indicates that pulmonary hypoplasia may actually precede uropathy (Smith et al, 2006). Peters and associates (1991) proposed a two-stage relationship with early pulmonary develop-

Figure 141-11. Sonographic image of left kidney in a newborn diagnosed with posterior urethral valves shows a large urinoma. The urinoma compresses the renal parenchyma inferiorly and is contained within the renal capsule.

ment being controlled by a “renal growth factor,” whereas lung growth and maturation in the later fetal period was more susceptible to the variations in amniotic fluid volume.

Urinomas

A urinoma is associated with posterior urethral valves in 3% to nearly 10% of cases (Fig. 141-11) (Greenfield et al, 1982; Patil et al, 2003). The introduction of renal ultrasonography in 1979 increased the detection of urinomas to 15% in one study (Heikkilä et al, 2011). Forniceal rupture will appear on renal ultrasonography as distorted renal parenchyma resulting from fluid trapped within the renal capsule, whereas transperitoneal transudation of fluid or bladder rupture will present as neonatal ascites (Greenfield et al, 1982). Although VCUG or radionuclide cystography may delineate the site of leakage for ascites, the cause is often difficult to determine (Patil et al, 2003).

Urinomas are usually addressed by restoring urinary flow and treating the proximate cause of LUTO, allowing the fluid to be reabsorbed. It is only in cases in which the ascites is causing respiratory distress, severe abdominal distention, or other clinical symptoms that percutaneous drainage or tapping of ascites becomes necessary; these interventions are uncommon.

There is some debate as to whether a urinoma heralds better or worse renal function for the affected side. Numerous studies have postulated that the urinoma serves as a pop-off mechanism, thereby reducing renal dysplasia on a given side, and some studies demonstrate globally preserved renal function, including an index of long-term renal severity (Rittenberg et al, 1988; Wells et al, 2010). Other studies hold that the urinoma, especially one retained within the renal capsule and compressing the kidney, impairs ipsilateral renal function and is a harbinger for worsened renal prognosis or has no bearing at all on long-term renal function (Patil et al, 2003; Kleppe et al, 2006; Heikkilä et al, 2011).

Delayed Presentation

In the age of extensive antenatal ultrasonography, delayed postinfancy presentation of posterior urethral valves is assumed to be less common. Still, Engel and colleagues (2011) reported that 141 of 228 children (62%) undergoing valve ablation presented with posterior urethral valves with a clinical presentation other than prenatal hydronephrosis or oligohydramnios. Up to 64% of these children had a normal prenatal ultrasonography and most presented with urinary tract infections, voiding complaints, and acute renal failure

in 10% (Engel et al, 2011). Another recent study at the Children's Hospital of Philadelphia followed a cohort of 138 patients presenting with posterior urethral valves between 1988 and 2011, of whom 60 (43%) presented after 6 months of life (Pulido et al, 2013). A high degree of suspicion for posterior urethral valves is therefore still warranted in boys presenting with lower urinary tract symptoms, especially recurrent urinary tract infections but also overflow incontinence, gross hematuria, renal dysfunction, and less commonly ejaculatory dysfunction (Bomalaski et al, 1999; Schober et al, 2004). A renal sonogram in these patients often detects the telltale bladder wall thickening and distal ureteral dilation that requires a voiding cystourethrogram for confirmation.

KEY POINTS: DIAGNOSIS, CLINICAL PRESENTATION, AND MANAGEMENT

- Antenatal finding of a thickened bladder and bilateral ureterectasis should be evaluated with early postnatal ultrasonography and voiding cystourethrogram.
- VCUG in a posterior urethral valve patient will show bladder wall irregularity, hypertrophied and elevated bladder neck, and dilated and elongated posterior urethra.
- The most common cause of early mortality in infants with posterior urethral valves is pulmonary hypoplasia.

SURGICAL INTERVENTION

Valve Ablation

Today, cystoscopy with ablation of the valves is considered the preferred initial surgical option in any neonate diagnosed with posterior urethral valves. The treatment goal is to restore flow of urine through the urethra and enable normal cyclic filling and emptying of the bladder, which is superior to urinary diversion and passive urine drainage (Smith et al, 1996; Close et al, 1997). Experimental models corroborate clinical evidence of the importance of bladder cycling, and one model of urinary diversion and undiversion demonstrated the changes that occur in a diverted bladder prevented from cycling (Chun et al, 1989). A fetal sheep model developed an increase in expression of extracellular matrix elements and apoptosis following a high diversion (Chun et al, 1989).

There are several approaches to valve ablation, which has historically been successfully completed even with a crochet hook passed retrograde into the urethra and feeling the hook catch the obstructing tissue. Innes Williams first described the engagement of valves with a hook, and Whitaker and Sherwood (1986) modified the hook by insulating the wire except for the very distal portion of the hook, which measures 6 to 7 Fr and could be passed at the bedside without general anesthesia while applying a small amount of diathermy when ablating the valves.

With the miniaturization of endoscopes in the age of fiberoptic and now digital technology, cystoscopy can be accomplished in even the smallest neonate and endoscopic valve ablation is the preferred approach at most centers today. Availability of a 7.5- or 9-Fr infant cystoscope with an offset lens facilitates passage of a variety of ablating devices, including a Bugbee electrode that can be used to incise the valves at the ventral 5 o'clock and 7 o'clock positions with or without an incision at the dorsal 12 o'clock position. Alternatively, the valves may be incised at the 12 o'clock position alone. A wire bent at the tip and passed through a 3-Fr ureteral catheter is another option, as is the visually guided Fogarty embolectomy catheter (Soliman, 2009). In an infant with a normal-caliber urethra, the 9.5-Fr resectoscope may be used with a Collins knife working element (Fig. 141-12).

Posterior urethral valves are thin and associated with minimal vascularity, and aggressive resection should be avoided. Use of a hot loop resectoscope for valve ablation, primarily in older children

in whom a resectoscope can be readily inserted, seems to be associated with a higher risk of urethral stricture and caution should be exercised with its use (Sarhan et al, 2010).

A urethral catheter is typically placed for at least 24 hours after the procedure. It is not necessary, though it is not uncommon, for the catheter to be left in for a longer period while the infant continues to be monitored for improvements in renal parameters or respiratory issues, often in an intensive care environment. A VCUG must be repeated after valve ablation within 1 month to ensure that the valves are no longer visible. It is not uncommon to see immediate signs of diminished bladder pressures, including some improvement in renal dilation and in the volume of vesicoureteral reflux.

Bladder neck hypertrophy and the subsequent elevation of the bladder neck dorsal to the posterior urethra, along with the incomplete emptying that seems to persist on imaging in some boys after valve ablation, prompted an interest in transurethral incision of the bladder neck during or after primary valve ablation (Androulakakis et al, 2005; Kajbafzadeh et al, 2007). Although some studies confirm that the bladder neck incision benefits emptying in children with neurogenic bladder, concerns of retrograde ejaculation and the lack of improvement compared to controls in even short-term pilot studies have limited the adoption of this technique until longer-term data are available (Christensen et al, 1985; Sarin and Sinha, 2013).

Vesicostomy

With miniaturization of endoscopic technology, vesicostomy is reserved primarily for the very low-birth-weight infant whose urethra cannot accommodate an endoscope, as well as a child with continued impaired renal function, high bladder urine volumes, and upper tract deterioration after valve ablation or urethral catheterization. The vesicostomy does reduce bladder storage pressures and may optimize glomerular filtration rate in some cases (Kim et al, 1997). The argument that the vesicostomy defunctionalizes the bladder and leads to decreased compliance in the long term has been refuted, since a properly created vesicostomy allows bladder filling and preserves contractile function because urine must be expelled through the stoma, albeit at a reduced leak point pressure (Hutcheson et al, 2001). The vesicostomy is best seen as a temporary diversion in children with posterior urethral valves because it does not alter clinical outcomes as compared to primary ablation, nor does it prevent a bladder from acting as an adequate reservoir for a renal transplant (Fine et al, 2011).

The vesicostomy is classically created with a 2-cm midline transverse incision made midway between the pubic symphysis and the umbilicus (Fig. 141-13). The rectus muscles are separated, the bladder is exposed with traction sutures, and the peritoneum is mobilized cephalad and away from the posterior wall and dome of the bladder. The bladder dome is identified by isolating the urachus, which is ligated so that the dome can be exposed through the fascial incision. The urachus and a small portion of the bladder dome are excised and the detrusor is then sutured to the fascia 1 cm below the edge of the cystostomy. The key operative step in creation of the vesicostomy is to ensure that the posterior wall of the bladder is taut—accomplished by bringing the dome of the bladder to the skin—to prevent prolapse of the back wall of the bladder through the incision (Hutcheson et al, 2001).

Upper Tract Diversion

Proponents of supravescical urinary diversion hold that direct decompression of the kidney by a cutaneous ureterostomy or pyelostomy will produce direct, low-pressure urinary drainage, allowing optimization of renal function (Fig. 141-14). High diversion, when renal dilation and biochemical markers of renal function fail to improve despite maximal bladder drainage, historically was believed to protect the upper urinary tract from ureterovesical junction obstruction caused by a tortuous intramural ureter passing through a thickened valve-affected bladder. In those cases, a loop

diversion of the ureter or renal pelvis, for example, also allows bladder filling and bladder cycling, mitigating the concern of defunctionalizing the bladder (Pinto et al, 1978; Churchill et al, 1990; Kim et al., 1997).

Contemporary studies and long-term follow-up of these patients, however, failed to detect a long-term renal protective benefit of high diversion, which necessarily requires an often complicated undiversion procedure as the child matures (Smith et al, 1996). Moreover, the finding that renal biopsies taken at the time of high urinary diversion uniformly show renal dysplasia, while the diversion does not seem to protect from renal failure, suggest that renal dysplasia occurring in early fetal development is the primary mediator of renal outcome, rather than any type of complex surgical undertaking in the neonate (Tietjen et al, 1997).

Upper urinary tract diversion may be considered in an infant with complete decompression of the lower urinary tract but worsening renal function, increasing upper tract dilation, and possibly a clinical picture of sepsis. Whether upper urinary tract diversion or vesicostomy preserves renal function better than valve ablation alone cannot be definitively concluded because of the lack of controlled comparative studies or other available studies. Still, upper urinary tract diversion will require secondary surgery, and the bladder may be exposed to a potentially extended period of defunctionalization with attendant risks of impairment

in compliance and contractility (Close et al, 1997). The preferred initial surgical intervention for infants with posterior urethral valves is endoscopic valve ablation. The clinician should be prepared to create a properly constructed vesicostomy or upper urinary tract diversion when primary valve ablation is impossible, or bladder decompression is not achieved by urethral catheterization or valve ablation alone.

Circumcision

A urinary tract infection can quickly progress to pyelonephritis and sepsis in an infant with posterior urethral valves because of the associated morbidities of vesicoureteral reflux, incomplete bladder emptying, and severe upper urinary tract dilation. The overall risk of urinary tract infection in children with posterior urethral valves is 50% to 60%—several magnitudes greater than the 1% risk for unaffected boys (Mukherjee et al, 2009; Bader and McCarthy, 2013). Circumcision reduces that risk of urinary tract infection by 83% to 92%, a reduction to a level of risk similar to that for unaffected boys (Wiswell et al, 1988; Mukherjee et al, 2009). It is recommended that a circumcision be strongly considered as a prophylactic measure for any boy diagnosed with posterior urethral valves, and it should certainly be completed before giving any consideration to a ureteral reimplant in a scenario

of frequent febrile urinary tract infections despite conservative measures.

Nephroureterectomy

Nephroureterectomy was historically considered an appropriate intervention for posterior urethral valve patients manifesting elements of the VURD syndrome discussed previously. The nonfunctioning renal unit in association with dilating urinary reflux was long considered a potential source for infections and sepsis, and prophylactic excision was considered appropriate. In contemporary practice, a focus on proper bladder emptying and circumcision has decreased the incidence of urinary tract infections sufficiently that

nephroureterectomy is rarely considered. Indeed, renal preservation is appropriate for even poorly functioning renal units contributing moderate polyuria, which is easier to manage than anuria. If frequent urinary tract infections localizing to the nonfunctioning renal unit necessitate a nephrectomy, preserving the ureter for potential subsequent reconstruction, such as a ureteral augmentation, is recommended (Husmann et al, 2004).

MANAGEMENT OF VESICoureTERAL REFLUX

A voiding cystourethrogram will reveal vesicoureteral reflux (see Fig. 141-9) in 50% to 80% of infants undergoing a workup for posterior

Figure 141-13. Blocksom technique for performance of cutaneous vesicostomy. A, An incision is made at a point midway between the umbilicus and pubis that corresponds to the upper limit of the filled bladder. B, A transverse incision is made in the rectus fascia and the bladder detrusor muscle is exposed. C, Stay sutures or noncrushing clamps are used to mobilize the bladder while dissecting the peritoneum away from the bladder dome. D, The dome of the bladder is identified by ligating the urachal remnant.

Figure 141-13, cont'd E, A transverse incision is then made in the dome of the bladder. F, The bladder detrusor is sutured to the rectus fascia, placing these sutures 1 cm away from the edge of the bladder incision. G, The bladder opening is sutured to the skin. (From Gonzales ED. Posterior urethral valves and other ureteral anomalies. In: Walsh PC, Retik AB, Vaughan ED, et al, editors. *Campbell's urology*. 8th ed. Philadelphia: Saunders; 2002.)

KEY POINTS: SURGICAL INTERVENTION

- Cystoscopy with valve ablation is the preferred initial treatment for posterior urethral valves.
- Vesicostomy does not inhibit bladder cycling, because the bladder continues to contract, but is reserved for select cases in which valve ablation is not possible.
- High urinary diversion offers no renal protective benefit and requires a complex secondary procedure to reverse the diversion.
- Circumcision should be encouraged as a prophylactic measure for a child with posterior urethral valves, and especially any boy with a history of urinary tract infection.

urethral valves (Puri and Kumar, 1996; Tournchi et al, 2014). Infants with valves are also at an increased risk for urinary tract infections as discussed in the previous section, and the coexistence of reflux and valves presents a clinical scenario that may suggest a role for ureteral reimplantation. However, understanding that reflux in these infants is a consequence of obstruction and the secondarily elevated bladder pressures is critical to management, and should render the ureteral reimplantation an option in atypical cases in which urinary tract infections continue despite maximal bladder therapy. Indeed, ablation of the valves or vesicostomy alone will resolve ureteral reflux in 25% to 40% of patients with urinary reflux prior to ablation (Hassan et al, 2003; Tournchi et al, 2014).

Hassan and colleagues (2003) found that the presence of urinary reflux did not correlate with renal outcomes, underscoring that the presence of reflux alone should not be seen as an indication for intervention. All efforts in a symptomatic posterior urethral valve

Figure 141-14. The variety of urinary tract diversions useful in posterior urethral valves. **A**, Vesicostomy. **B**, Distal ureterostomy. **C**, Proximal loop ureterostomy. **D**, Cutaneous pyelosotomy. **E**, Ring ureterostomy. **F**, Sober Y ureterostomy. (From Glassberg KI, Horowitz M. Urethral valves and other anomalies of the male urethra. In: Belman AB, King LR, Kramer SA, editors. *Clinical pediatric urology*. 4th ed. London: Martin Dunitz; 2002. p. 899–945.)

patient with vesicoureteral reflux must focus on addressing any persistent bladder outlet obstruction, reducing intravesical pressures by considering anticholinergic treatment, and treating underlying bladder dysfunction that is common in bladders exposed to fetal bladder outlet obstruction. Urodynamic evaluation may help guide management in this regard (Kim et al, 1997).

In the rare event that a clinical scenario of recurrent urinary tract infections mandates intervention in a child with posterior urethral valves, bladder management in advance of intervention is a critical component in ensuring favorable surgical outcomes (Hunziker et al, 2012).

Consideration of surgical correction for reflux must also recognize the higher complication rate of stricture and persistent reflux associated with reimplanting dilated ureters into thick-walled bladders that are not properly rehabilitated prior to surgery (Coleman and McGovern, 1978; Atwell, 1983). Indeed, any treatment of urinary reflux in a child with profound bowel dysfunction—as commonly seen in boys with posterior urethral valves—potentially puts an already compromised renal unit at risk for further deterioration (Sillén et al, 2010; Tekgül et al, 2012). Endoscopic correction of reflux seems to carry less of the risks of myogenic disruption and renal deterioration seen with ureteroneocystotomy in children with valves, but the overall surgical success rate is lower than that for children without valves (Puri and Kumar, 1996; Tourni et al, 2014).

BLADDER DYSFUNCTION AND VALVE BLADDER SYNDROME

Consequent to exposure to obstruction from its earliest development, the bladder is necessarily the focus of management and rehabilitation throughout the life of a boy diagnosed with posterior

urethral valves (Parkhouse et al, 1988). The extent of remodeling and subsequent functional compromise may vary, but the bladder and its dysfunction begin a cascade of pathophysiologic changes, including voiding dysfunction, urinary reflux, and worsening of renal dysplasia and obstructive uropathy. The ultimate manifestation of this dysfunction is the valve bladder syndrome.

Urodynamics plays an important role in monitoring an affected child's progression through various well-described changes in bladder function throughout childhood. The bladder evolves through three distinct contractility patterns through childhood: (1) detrusor hyperreflexia in infancy and early childhood; (2) decreasing intravesical pressures and improved compliance bladder in childhood; and (3) increased capacity bladder with hypocontractility and atony in adolescence (Peters et al, 1990; De Gennaro et al, 2000). Holmdahl and coworkers (1995) stressed that the patterns outlined here overlap in most children, emphasizing that the patterns are not arbitrary but rather are useful guideposts in monitoring and managing children over the long term.

Mitchell (1982) conceptualized a vicious circle in voiding dysfunction wherein the outlet obstruction begins a cascade of events leading to the end-stage bladder, or valve bladder. Bladder outlet obstruction leads to detrusor hypertrophy, which increases the voiding pressures initially as the bladder strives to complete emptying. As further remodeling of the bladder occurs, however, the post-void residual begins to increase as the urine output increases. Ultimately, the bladder cannot meet the demand of emptying and the detrusor decompensates.

Bladder dysfunction, even when not detected on clinical history alone, must always be suspected in children with a history of valve ablation. One systematic review of 34 studies describing renal function, vesicoureteral reflux, and urodynamic findings after endoscopic valve ablation in 1474 patients found that, whereas the self-reported history of incontinence ranged

widely between 0% and 70%, the mean incidence was 19%. However, when urodynamic outcomes were examined, the incidence of bladder dysfunction rose to a mean of 55% (Hennus et al, 2012). Reliance on clinical examination or patient questionnaires alone may grossly underestimate bladder dysfunction, and obtaining a uroflow and checking postvoid residuals should be a routine part of follow-up in toilet-trained children with a history of posterior urethral valves. Upper tract assessment with renal ultrasonography can also be a useful, simple tool to detect dangerous bladder dysfunction and monitor response to therapy (Lopez Pereira et al, 2013).

Bladder Management

The typical follow-up for children with posterior urethral valves after ablation for bladder dysfunction has focused on observation, clinical history, and urodynamics. Education of parents and growing children is a critical component of bladder management and the success of any prescribed behavior modifications. Families are counseled to not aggressively push an affected child toward toilet training and to expect a lag compared to the normal population. Daytime incontinence is not uncommon, ranging from 7% to 35%, and nocturnal enuresis is expected in 1 of 4 children with a history of valve ablation (Hennus et al, 2012). Once toilet training is achieved, children and caregivers are educated to ensure adequate fluid intake, to void on a timed regimen, and to practice double voiding. Biofeedback therapy and home pelvic floor exercises have also been shown to be useful (Ansari et al, 2008).

The role of adjunctive medications is unclear. The preferred intervention is predicated also on varying proposed etiologies of voiding dysfunction after valve ablation: (1) functional obstruction at the bladder neck as a result of hypertrophy and external sphincter hyperreflexia, or (2) bladder wall thickening caused by detrusor wall thickening from increased collagen deposition. One study suggests the use of α -adrenergic blockade to relieve sphincteric hypertonicity and relax the bladder neck in children with high postvoid residuals, finding a significant reduction in residual volumes (Abraham et al, 2009). In contrast, Casey and coworkers (2012) administered oxybutynin at 0.1 mg/kg twice daily in 18 consecutive infants undergoing urodynamic assessments at 3 months after valve ablation and showing high voiding pressures or small bladder capacity. Although the study found that both of these parameters improved significantly with oxybutynin, the lack of a control group in both afore-

mentioned studies and the reality that detrusor hypercontractility and elevated voiding pressures are normal findings in neonates necessitate more rigorous prospective studies (Sillén et al, 1992; Casey et al, 2012). If oxybutynin is chosen, its use must be closely monitored for effect, and if a growing child begins to demonstrate higher bladder residual volumes and capacity, oxybutynin should be stopped. Therapy was stopped in 4 of 18 patients in the Casey and coworkers (2012) study, and another study found that myogenic failure required intermittent catheterization (Kim et al, 1997). It is unclear whether the myogenic failure was a consequence of evolving bladder dysfunction inherent to posterior urethral valves or secondary to oxybutynin, but caution nevertheless should be exercised during the treatment period.

Valve Bladder Syndrome

The term *valve bladder syndrome* was coined by Mitchell in 1982 after reviewing his experience with 11 patients in whom hydronephrosis and renal function continued to worsen despite no clinical evidence of residual bladder outlet obstruction (Lloyd et al, 2013). Mitchell's concept, which is illustrated in Figure 141-15 and was described earlier, holds that although the bladder initially compensates for outlet obstruction by generating high voiding pressures, it begins to experience higher volumes of urine as a result of increasing urine production as the child grows. The polyuria caused by nephrogenic diabetes insipidus secondary to evolving renal impairment augments the urine volumes entering a bladder that is increasingly unable to empty completely. As the postvoid residuals increase, the bladder no longer enjoys periods of complete relaxation, and the detrusor fibers are continuously in a state of partial or complete stretch, beginning a cascade of gene expression and phenotypic changes that further impair contractility of the bladder (Kirsch et al, 2003; Hutcheson et al, 2004; Shukla et al, 2004). When the bladder does empty partially, the urine already stored in the hydronephrotic kidneys quickly empties into the bladder once again, denying the detrusor muscle periods of relaxation. The impaired contractility and increasing postvoid residuals then transmit the increasing bladder pressures to the kidneys, potentially worsening the already impaired renal function.

In sum, then, three processes contribute toward the devolution of a bladder into a valve bladder in a cohort of patients with posterior urethral valves: (1) polyuria. (2) poor bladder

Figure 141-15. The valve bladder “vicious cycle.” An affected bladder will lead to increasing postvoid residuals (PVR). The sustained stretch will cause increasing collagen deposition and other changes that cause increased pressures to be transmitted to the renal pelvis. Subsequent renal tubular injury causes polyuria and increased volume in the bladder that already empties poorly, and the cycle continues, leading to additive damage.

compliance with high-pressure voiding and elevated wall tension bladder, and (3) residual urine volume. These three factors conspire to sustain the bladder overdistention that is the original insult leading to the valve bladder (Koff et al, 2002).

Although the goal of intensive management of bladder dysfunction is to arrest the progression toward full expression of late-term manifestations of valve bladder syndrome, *valve bladder syndrome* is actually a broad term describing a continuum of symptoms of bladder dysfunction. As described in the previous section, monitoring urine postvoid residuals, flow rates, and voiding pressures, along with timed voiding, double voiding, and anticholinergics or α -blockers, comprises the mainstay of treatment. Clean intermittent catheterization (CIC) becomes necessary if myogenic failure progresses.

Overnight bladder drainage is an important adjunct in therapy, and increasingly adopted as a standard intervention in children with classic evidence of developing a valve bladder syndrome (Koff et al, 2002; Nguyen et al, 2005b). Nocturnal bladder drainage is instituted if ureteral dilation and hydronephrosis do not respond to behavior modification, or an affected child develops worsening renal function or recurrent urinary tract infections. The continuous bladder drainage achieved by leaving a urinary catheter in the bladder over a 7- to 10-hour period allows an extended period of bladder decompression even as the kidneys empty urine without encountering the increased voiding or resting bladder pressures they face during the day. This simple step interrupts the “vicious cycle” of bladder remodeling and consequent renal effects resulting from chronic bladder distention. Koff and colleagues (2002) and Nguyen and associates (2005a) both noted significant improvements in hydronephrosis, continence, and urinary tract infections after instituting overnight bladder drainage.

When CIC or overnight bladder drainage is difficult because of an elevated bladder neck or sensate urethra, an appendicovesicostomy utilizing the Mitrofanoff principle (Mitrofanoff, 1980) presents a useful option. Minimally invasive techniques to create this catheterizable channel, utilizing both laparoscopic and robotic-assisted approaches, are increasingly being adopted at many centers (Mitrofanoff, 1980; Hsu and Shortliffe, 2004; Nguyen et al, 2009; Famakinwa and Gundeti, 2013; Famakinwa et al, 2013). The robotic-assisted approach potentially limits the field of dissection and could, in older children, make it difficult to mobilize the appendix and perform bladder mobilization with anastomosis of the appendix through a single robot docking. In such situations, a pure laparoscopic approach could be used to mobilize the appendix, followed by docking of the robot with standard triangulation of port sites focused on the pelvic midline for anastomosis of the appendix.

Augmentation cystoplasty is rarely utilized for a valve bladder in the contemporary era, perhaps because of improved understanding of bladder dysfunction, behavior modification, and timely institution of overnight bladder drainage. However, when faced with a small-capacity, high-pressure, thick-walled valve bladder with worsening upper tract anatomy refractory to conservative measures, augmentation may be considered. Ureteral augmentation is preferred in children with posterior urethral valves because it reduces the risks of mucus production, acidosis, and stones that are common to ileal augmentation. Moreover, severe ureteral dilation or unilateral VURD seen in boys with posterior urethral valves offers an ideal clinical scenario wherein the ureter can be detubularized and patched on a bisected bladder without bowel manipulation. Johal and coworkers (2008) reported lasting benefits of increased capacity and decreased filling pressures at a mean follow-up of 4.5 years after ureteral augmentation.

ANTENATAL MANAGEMENT

Antenatal intervention in cases of suspected LUTO was popularized in the mid 1990s as advances in fiberoptics and endoscopic miniaturization enabled even complex fetal procedures. Intervention is considered in some centers when antenatal sonography detects

KEY POINTS: MANAGEMENT OF VESICoureTERAL REFLUX, BLADDER DYSFUNCTION, AND VALVE BLADDER SYNDROME

- The focus of management for vesicoureteral reflux in a child with posterior urethral valves should be centered on the bladder, and ureteral reimplantation is rarely offered.
- The bladder evolves through three patterns in boys with posterior urethral valves: (1) detrusor hyperreflexia in infancy and early childhood, (2) decreasing intravesical pressures and improved compliance bladder in childhood, and (3) increased bladder capacity with hypocontractility and atony in adolescence.
- Overnight bladder drainage is considered in the scenario of increasing postvoid residuals, urinary tract infections, or worsening hydronephrosis and renal function.

evidence of oligohydramnios, a dilated bladder, and severe hydronephrosis—without renal cortical cystic lesions—in a fetus with a normal karyotype (Ruano, 2011). A fetal urine sample can also be obtained after 20 weeks' gestational age, and favorable prognosis is suggested by a urinary sodium less than 100 mEq/L, chloride less than 90 mEq/L, osmolarity less than 200 mEq/L, and β_2 -microglobulin less than 6 mg/L (Nicolini and Spelzini, 2001).

Vesicoamniotic shunting to treat oligohydramnios offers potential ameliorative effects on pulmonary function and represents the first stage in fetal intervention, with several hundred shunt procedures reported in the literature (Ruano, 2011). This approach is corroborated by fetal sheep models demonstrating that restoration of amniotic fluid volume prevents lung hypoplasia, though the lack of controlled studies in the literature constrains conclusions as to its effectiveness (Kitagawa et al, 2006). Also, although a systematic review published a survival advantage in infants having undergone vesicoamniotic shunting, randomized trials were lacking (Clark et al, 2003). The Percutaneous vesicoamniotic shunting versus conservative management for Lower Urinary Tract Obstruction (PLUTO) trial attempted to fill this void but was limited by poor recruitment and pregnancy terminations, with only 12 live births in each group studied. The results showed a trend toward improved survival at 28 days in the shunted group but overall survival was very poor in both groups, with only 2 infants surviving to 2 years of age with normal renal function. There was a high mortality owing to pulmonary hypoplasia. There was also a greater risk of pregnancy loss in the shunt group because of procedure-related complications and early rupture of membranes (Morris et al, 2013).

Biard and colleagues (2005) reported a mean 5.83 years of follow-up on 20 pregnancies with a singleton male fetus that underwent vesicoamniotic shunting for clear evidence of isolated LUTO and good or borderline urinary sampling parameters. This study found an overall 1-year survival of 91%, and health-related quality-of-life parameters were similar to those in the unaffected, healthy child population. Vesicoamniotic shunting, in contemporary practice, is utilized as a potential intervention in the rare case of LUTO with oligohydramnios but should be limited to experienced centers with multidisciplinary capabilities.

No studies similar to the PLUTO trial have been attempted for even more complex fetal interventions such as fetal cystoscopy with valve ablation, or even fetal surgery. Fetal cystoscopy, performed using a 1.0-mm fetoscope, is carried out in an antegrade fashion by a transuterine percutaneous incision into the bladder. When the posterior urethra is entered through the bladder neck, a Nd:YAG laser or cauterizing wire is used to perforate the obstructing membrane (Quintero et al, 1995, 2000; Ruano, 2011). Holmes and coworkers (2001) reported a series of 14 fetal surgical procedures for posterior urethral valves, including antenatal valve ablation, vesicoamniotic shunting, cutaneous ureterostomy, and vesicostomy.

Six infants died as a result of premature delivery and respiratory failure and 5 of 8 surviving children at a mean 11.6 years of follow-up were in renal failure. The 43% fetal mortality rate for fetal surgery must be an essential part of any prenatal counseling prior to considering fetal intervention that offers potential, though yet unproven, benefits for a very select group of pregnancies.

PROGNOSTIC INDICATORS FOR RENAL FUNCTION

Despite numerous advances in antenatal diagnosis and intervention, and rapid postnatal evaluation and treatment, the lifetime prevalence of end-stage renal disease in boys with posterior urethral valves is between 20% and 50% (Parkhouse et al, 1988; Smith et al, 1996; Sarhan et al, 2011). Risk factors known to affect the prognosis of an infant diagnosed with posterior urethral valves include age at diagnosis, renal dysplasia with or without vesicoureteral reflux, nadir creatinine during 1 year of life, recurrent urinary tract infections, and bladder dysfunction.

Nadir creatinine has long been considered a relatively easy method of predicting long-term renal outcome in affected children. The nadir creatinine value measured at 1 year of life appears to be more accurate as a predictive tool than the value obtained at 1 month of age (Drozd et al, 1998; Lal et al, 1999; Heikkilä et al, 2011). A serum creatinine of less than 0.8 mg/dL appears to indicate a minimal risk, whereas a value greater than 1.2 mg/dL at 1 year of age predicts a higher risk of developing end-stage renal failure (Drozd et al, 1998; DeFoor et al, 2008). In those studies suggesting that a 1-month post-treatment serum creatinine is a more accurate predictor of renal function, again the value of less than 0.8 mg/dL at 1 month after treatment seems to indicate better long-term outcomes (Rittenberg et al, 1988).

Age at diagnosis remains an unclear predictor of future renal outcomes. The assumption that antenatal diagnosis would lead to more rapid diagnosis of posterior urethral valves and therefore forestall renal injury has not been sustained. Indeed, Heikkilä and associates (2011) found that patients diagnosed in the pre-sonography era (before 1982) had a risk of end-stage renal disease of 16.8%, as compared to 36.6% developing renal failure if diagnosed during the post-sonography era. Another review found a similar variation with 41% of those presenting before 1 year of age having poor long-term renal outcome compared to 15% of those presenting after 1 year of age (Parkhouse et al, 1988). This difference in outcomes may be explained by the assumption that the critically ill infants in the pre-sonography era likely died before diagnosis was complete, and early interventions, including fetal measures, in the current era increased survival dramatically. These infants born after 1982 may previously have died and tended to have more severe manifestations of valve disease and related comorbidities contributing to worse renal outcomes.

Another common assumption, not corroborated, was that the later-presenting children likely had a milder variant of valve disease, allowing them to go undetected for some years before presenting with more vague symptoms of voiding dysfunction. However, some reports found much worse outcomes in children presenting outside of the neonatal period with posterior urethral valves, with delayed presentation associated with a significantly higher risk of azotemia, higher serum creatinine, and worse long-term renal outcomes (El-Sherbiny et al, 2002; Ziylan et al, 2006; Sarhan et al, 2011).

Quantifying renal dysplasia without a renal biopsy requires reliance on available imaging technology, including renal sonography and nuclear scintigraphy. Hyperechogenic kidneys, cystic changes in the cortex, and loss of corticomedullary differentiation are considered to portend a poor prognosis (Robyr et al, 2005). Pulido and colleagues (2013) examined the association of the renal parenchymal area—defined as the area of the kidney minus the area of the pelvicaliceal system on the first postnatal sonogram—with end-stage renal disease. Reviewing the first postnatal ultrasound images of 60 patients followed for 393 person-years, the authors found that, for infants with a serum creatinine between 0.8 and 1.1 mg/dL at 1 month of life, each 1-cm² increase in renal parenchymal area

was associated with a lower risk of end-stage renal disease (Pulido et al, 2013). The study highlights that there is a need for novel ways of predicting renal outcomes in children with posterior urethral valves, and certainly more definitive and powerful predictive tools may lie in the elucidation of genetic and biochemical markers (Farrugia et al, 2006).

TRANSPLANTATION IN POSTERIOR URETHRAL VALVE PATIENTS

The prevalence of end-stage renal disease in boys with a history of posterior urethral valves is up to 50%, and the 2006 annual report of the North American Pediatric Renal Trials and Collaborative Studies listed obstructive uropathy as the second most common cause for transplantation, accounting for 1424 of 8990 transplantation cases (15.8%) since 1987 (Smith et al, 2007).

Patients with posterior urethral valves comprise an especially difficult cohort for receiving a renal transplant. These boys are likely to have several comorbidities, including high-grade vesicoureteral reflux into native nonfunctioning kidneys and valve bladder syndrome with a thick-walled, poorly contractile or hypercontractile bladder. A pediatric urologist must be a critical component of the transplantation team and should carefully examine the prospective recipient as part of the pretransplantation evaluation. Transplant recipients in whom bladder dysfunction is incompletely managed or the bladder reservoir is not optimized have significantly higher complication rates and graft loss rates (Sheldon et al, 1994; Mendizabal et al, 2005).

Outcomes after renal transplantation in children with posterior urethral valves have been mixed. The thickened bladder wall of posterior urethral valve patients may contribute to the significantly increased incidence of ureteral obstruction on univariate and multivariate analysis compared to a non-posterior urethral valve transplantation cohort, but recent studies saw no risk of increased graft loss or patient death despite ureteral obstruction, stenting, or dilation (Indudhara et al, 1998; DeFoor et al, 2003; Smith et al, 2010; Fine et al, 2011). Fine and colleagues (2011) reported on 59 valve patients who underwent renal transplantation with 8-year follow-up and found that outcomes were similar whether a boy underwent an initial valve ablation, vesicostomy, or supravescical diversion; also, though bladder dysfunction increased the risk of graft failure, the effect did not reach significance.

Video-urodynamics should be obtained for transplant candidates to determine the safe storage pressures and contractile function of the future reservoir. Overnight bladder drainage or CIC may be initiated prior to transplantation to optimize the reservoir and establish proper bladder management skills that will be essential for graft success after transplantation. Pretransplantation nephrectomy is rarely required and only considered in cases in which proteinuria or severe polyuria is creating hemodynamic challenges.

If augmentation is believed necessary based on unsafe storage pressures in the bladder, this reconstruction can be considered before or after transplantation. Whereas previous dogma suggested that a pretransplantation augmentation is preferable to prevent the undertaking in an immunocompromised child or one too young to take responsibility for catheterization and pouch management, recent experience argues that transplantation into even a vesicostomy is a safe alternative until the child grows to an appropriate age for cystoplasty and the attendant reliance on CIC (Rigamonti et al, 2005; Christman et al, 2013).

QUALITY OF LIFE WITH POSTERIOR URETHRAL VALVES

It must be emphasized that posterior urethral valves have lifetime repercussions. Understanding these long-term risk factors and their impact on quality of life is necessary for counseling, preparing, and treating valve patients as they reach adulthood.

The evolution of the valve bladder and the associated comorbidities of renal transplantation that many valve patients face are

associated with well-known risks, including erectile dysfunction and infertility. The lower urinary tract symptoms that affect children with valves also affect them as adults two to three times more often than those symptoms affect the general population (Tikkinen et al, 2011). A survey of 67 adult patients with posterior urethral valves found that the overall rate of erectile dysfunction or infertility was not different than that in the general population (Taskinen et al, 2012). However, a subgroup analysis of these same patients with urinary incontinence or renal insufficiency showed that valve patients had the greatest evidence of impaired quality of life, underscoring the necessity of long-term follow-up and active treatment well into adulthood (Jalkanen et al, 2013). Indeed, the chronicity of bladder dysfunction, risk of urinary tract infections, and sequelae of renal dysfunction require communication between pediatric and adult urologists, even as the adult urologist should be knowledgeable of the pathophysiology of posterior urethral valves and well prepared to provide care to these patients after their transitions into adulthood.

KEY POINTS: ANTENATAL MANAGEMENT, PROGNOSTIC INDICATORS FOR RENAL FUNCTION, AND TRANSPLANTATION IN VALVE PATIENTS

- An antenatal vesicoamniotic shunt can be considered in selected patients with bladder wall thickening, hydronephrosis, and oligohydramnios. Although it may reduce the severity of pulmonary hypoplasia, the procedure confers limited protection from renal impairment.
- A nadir serum creatinine at 1 year of less than 0.8 mg/dL confers a significantly decreased risk of developing end-stage renal disease.
- Transplantation into a valve-affected bladder may carry a higher risk of ureteral obstruction, but there is no increased risk of graft loss compared to controls.

OTHER URETHRAL ANOMALIES

Anterior Urethral Valves

Anterior urethral valves are the most common congenital obstructive lesion of the anterior urethra, but are 25 to 30 times less common than posterior urethral valves (Confer et al, 2010). Since the condition is often found in association with a large anterior urethral diverticulum, the valve itself is variously described as an obstruction resulting from a wall of the diverticulum obstructing flow or a semilunar fold draping down from the wall of the anterior urethra and interrupting urinary flow (Tank, 1987; Paulhac et al, 2003). The embryology of anterior urethral valves is not clear, but abortive corpus spongiosum over the affected portion of the anterior urethra indicates a place on the hypospadias spectrum or a faulty union between urethral mucosa and the epithelium of the fossa navicularis. A rupture of dilated bulbourethral glands has also been suggested as an etiology (McLellan et al, 2004). The valves may be located at the bulbar urethra, the penoscrotal junction, or the penile urethra (Firlit et al, 1978).

Patients present with anterior urethral valves at different ages based on the severity of the obstructive process. Symptoms may consist of postvoid dribbling and mild incontinence, significant bulging of the distal penis, palpable bladder with obstruction or even renal insufficiency, and urinary tract infections (Cruz-Diaz et al, 2013). Diagnosis requires a careful examination of the external genitalia, and compression of the distal shaft may result in expressing of urine as seen in a diverticulum. A voiding cystourethrogram is required to confirm the diagnosis and may demonstrate a dilated anterior urethra with proximal signs of chronic obstruction, including bladder diverticula and massive vesicoureteral reflux.

The treatment approach to anterior urethral valves varies according to age of presentation, extent of upper tract damage, and extent of anterior urethral deformity. In a premature or small infant, a vesicostomy may be required to facilitate relief of obstruction until the infant can accommodate a cystoscope or undergo further reconstruction. In the majority of cases, cystoscopy with valve ablation using a Bugbee electrode or laser is possible as an initial treatment, and when successful, no further surgery of the urethra is required (Cruz-Diaz et al, 2013). In more severe cases in which a gross urethral diverticulum is seen, surgical reconstruction over a urethral catheter may be required.

Up to 80% of children with anterior urethral valves will develop bladder dysfunction, and bladder instability, hyperreflexia, and diminished compliance and capacity will be seen on urodynamics (Kajiwaru et al, 2007). As with posterior urethral valves, long-term renal function is contingent upon preoperative creatinine and glomerular filtration rate. Routh and colleagues (2010) performed a multivariate analysis of data available from 97 studies including 229 patients with anterior urethral valves and found that pretreatment azotemia, vesicoureteral reflux, and urinary tract infection together increased the risk of poor renal outcome 25-fold. Still, because of the milder and more subtle presentation, the overall incidence of preserved renal function in anterior urethral valves is better than that in posterior urethral valves, with 78% of patients having normal renal function after treatment (Routh et al, 2010).

Urethral Atresia

Urethral atresia or congenital urethral stricture is a rarely described entity, likely because of its high associated mortality. When an infant survives—because the obstruction is incomplete or because there was decompression owing to an antenatal shunt placement or a patent urachus—the outcome can be similar to that of a child with obstructing posterior urethral valves (González et al, 2001). An obstructing membrane is typically seen at the distal end of the prostatic urethra and the urethra distal to that point may be hypoplastic. As a part of the LUTO spectrum seen in antenatally detected anomalies of the lower urinary tract, the obstruction is confirmed after birth with cystoscopy (Fig. 141-16) and a vesicostomy is usually required (Freedman et al, 1999).

Figure 141-16. Cystoscopic image on the second day of life in a neonate with a prenatal history of lower urinary tract obstruction. Cystoscopy demonstrates a near-complete urethral obstruction in the mid-bulbar urethra most consistent with urethral atresia.

Figure 141-17. A to J, Variations of urethral duplications shown in the sagittal plane. Each of these drawings shows the ventral urethra as the functional one as it passes through the prostate and sphincter. (From Colodny A. Urethral lesions in infants and children. In: Gillenwater JT, Howards SS, Duckett JW, editors. *Adult and pediatric urology*. 2nd ed. St. Louis: Mosby; 1991. p. 2013.)

Whether urethral atresia is a precipitating factor for development of prune-belly syndrome in certain cases remains controversial, but infants with urethral atresia or congenital urethral stricture often will present with oligohydramnios, bilateral hydroureteronephrosis, and weak abdominal wall musculature. The progressive augmentation by dilating the urethra anterior (PADUA) procedure is considered a safe alternative for restoring urethral continuity in selected cases without complex reconstructive surgery (Passerini-Glazel et al, 1988; Stalberg and González, 2012).

Urethral Duplication

Urethral duplication is another rare anomaly of the urethra with several known anatomic variants. The duplication may begin at the bladder neck or within the more distal urethra. Whereas one urethra usually terminates on the glans near its orthotopic position, another urethra may end in a meatus placed on the glans or more ventrally along the shaft of the penis. In the most severe cases, the duplicated urethra may even be as proximal as the anal sphincter. The duplication occurs in a sagittal plane, with the ventral urethra usually the functional meatus containing the sphincteric complex and verumontanum.

Effmann and associates (1976) are credited with the most widely used classification system for urethral duplications. Broadly, the type I abnormality includes a blind incomplete urethral duplication or accessory urethra. Type II is a complete patent urethral duplication with four subtypes and type III refers to urethral duplication as a component of partial or complete caudal duplication (Fig. 141-17). The Y-type duplication refers to a type IIA2 in which the duplicated urethra arises from the first urethra but diverges away to open into a second meatus that opens as ventral as the rectum.

Diagnosis is readily made in some cases when two distinct meatal openings are seen on the glans, but in other cases requires a high index of suspicion when examining what appears to be an atypical case of proximal hypospadias with a patent-appearing opening on the glans. A voiding cystourethrogram will confirm the diagnosis during the voiding phase in many cases, though a retrograde injection of the distinct urethra can also be accomplished (Fig. 141-18) (Hoekstra and Jones, 1985; Podesta et al, 1998).

Surgical management is complex and may require a variety of single or multiple-stage repairs. Whereas the small, blind-ending accessory urethra may be treated expeditiously with simple coagulation of the mucosal tract with a Bugbee electrode, a patent duplicated urethra connected to the bladder with a distinct bladder neck will require a planned reconstruction. When two urethral openings

Figure 141-18. A, Voiding cystourethrogram image demonstrates a type IIA2 urethral duplication with two noncommunicating urethral channels passing through the urogenital diaphragm. B, Intraoperative photo of same patient showing two distinct urethral openings that were noted on the glans penis and are cannulated separately.

are found on the glans, the more dorsal urethra may mimic the appearance of a distal epispadias. [Alanee and colleagues \(2012\)](#) recently described a technique by which the septum between the two urethral channels is incised and the dorsal defect is repaired with reverse glans wings to cover a dorsal urethroplasty. In cases in which the urethral openings are separated by the Y-type arrangement, a staged reconstruction using preputial or buccal mucosa flaps is often required to bring the more ventral, but functional, meatus to the glans penis where it can be insinuated into the dorsal, usually atretic, urethra. The anterior sagittal trans-ano-rectal approach (ASTRA) is also recommended as a means to mobilize the meatus placed in the anal sphincter ([Macedo et al, 2012](#)).

Urethrorrhagia

Urethrorrhagia, usually referred to as idiopathic urethrorrhagia, describes a spotting of blood on the underwear after urination, or voiding of clear urine followed by a few drops of blood. The visible blood tends to raise alarm within families, but the condition is typically considered benign and self-limited. Urethrorrhagia is most commonly seen in boys.

The etiology of urethrorrhagia is unclear, though various hypotheses have been offered. Meatal stenosis and dysfunctional elimination syndrome have been suggested as inciting factors ([Herz et al, 2005](#)). Proponents of voiding dysfunction as the etiology of urethrorrhagia hold that increased voiding pressures caused by incomplete relaxation of the external urethral sphincter lead to turbulent flow that creates a negative intraluminal urethral pressure. That negative pressure causes an engorgement of the sinuses of the urethral mucosa and a small extravasation of blood ([Docimo et al, 1998](#); [Herz et al, 2005](#)). Meatal stenosis is similarly proposed as a cause of increased voiding pressures.

Adult urologists consider cystoscopy and upper urinary tract evaluation a necessary step for the evaluation of hematuria, but the high rate of spontaneous resolution of urethrorrhagia in symptomatic adolescent males—up to 92%—means that routine cystoscopy is not necessary. Rather, evaluation should focus on a detailed history of bowel and bladder function, renal and bladder ultrasonography, and an office evaluation of urinary flow rate and postvoid residual. If urethrorrhagia becomes atypical—accompanied by symptoms of urethral stricture or increased urethral bleeding—then cystoscopy should be performed.

Although the majority of cases of urethrorrhagia will have an idiopathic origin, urethral strictures are diagnosed during evaluation in 14% to 60% of patients ([Dewan and Wilson, 1996](#); [Poch et al, 2007](#)). This strong association has led to some debate as to whether cystoscopy itself, in traversing abnormal inflamed epithelium, initiates stricture formation. [Poch and associates \(2007\)](#), in a review of 66 boys with urethrorrhagia, found that cystoscopy in atypical cases of urethrorrhagia identified varying levels of bulbar urethral inflammation, with 24% of patients having a white membranous exudate noted at cystoscopy subsequently being diagnosed with a urethral stricture over a mean of 5 years. In the same cohort, 12% had a stricture found on cystoscopy without any prior history of instrumentation. These findings seem to support a perspective that, although cystoscopy is benign in most cases, the procedure may exacerbate the inflammation of an already inflamed urethra in a small population that cannot readily be distinguished by any radiologic modality. A careful analysis of voiding habits and baseline uroflow is therefore imperative before cystoscopy is considered ([Poch et al, 2007](#)).

Urinary Fistula in Boys with Anorectal Malformation

The vast majority of boys born with anorectal malformation will have a rectal fistula to the urinary tract ([Hong et al, 1992](#)). Since the initial diverting colostomy is completed during the neonatal period, the fistula tract is usually seen on distal colostogram during subsequent workup prior to anorectoplasty (Fig. 141-19).

Figure 141-19. Voiding cystourethrogram in a male infant with an anorectal malformation demonstrates passage of contrast into the rectum via a patent, though small, urethrorectal fistula visualized on the voiding phase of the study.

Pediatric urologists are an integral part of any multidisciplinary team caring for children with anorectal malformations. Because associated genitourinary anomalies range from 25% to 50%, routine diagnostic imaging to determine the presence of renal anomalies and vesicoureteral reflux is recommended ([Hoekstra et al, 1983](#)). A recent analysis of 190 patients with anorectal malformations found that 31 (16.3%) developed a febrile urinary tract infection; of these, 51.6% had a diagnosis of vesicoureteral reflux. On multivariate analysis the presence of genitourinary malformations was associated with a urinary tract infection, but the association did not reach statistical significance ([Sanchez et al, 2014](#)).

When definitive surgical repair is planned in association with general pediatric surgeons, a posterior sagittal approach is preferred to address the rectourethral fistula concurrently. Care must be taken to properly identify the fistula tract and ensure that the tract is excised adjacent to the urethra as well as the rectum, to ensure complete removal of excess tissue that could become a diverticulum if not resected completely.

A urologist is present at the time of anorectoplasty and fistula repair, and the procedure begins with cystoscopy with an attempt to pass an open-ended ureteral catheter through the fistula tract. A guidewire may also be passed if the caliber of the fistula is small. A urethral catheter is then placed into the bladder, across the urethra. Once the child is placed prone, and posterior sagittal anorectoplasty begins, the rectum is adequately mobilized away from the urethra using the previously placed catheter as a guide to location. The fistula tract is excised completely, and the urethral defect is approximated as close to the urethra as possible, reducing the risk of a urethral diverticulum. The rectal defect may be closed primarily, but if redundant intestinal tissue is available, then the fistulous portion of intestine is excised. Healthy adjacent tissue is interposed and the catheter is left in place for at least 1 week to ensure healing of the urethroplasty.

The complete reference list is available online at www.expertconsult.com.

KEY POINTS: ANTERIOR URETHRAL VALVES, URETHRAL ATRESIA, URETHRAL DUPLICATION, URETHRORRHAGIA, AND ANORECTAL MALFORMATION

- Anterior urethral valves and urethral atresia are less common causes of LUTO, and outcomes can be similar to those of posterior urethral valves if the neonate survives.
- Dysfunctional voiding causing a turbulent urinary flow may lead to urethrorrhagia.
- Treatment for urethrorrhagia should focus on improving voiding habits and conservative management, reserving cystoscopy for refractory cases and when there is significant straining during voiding.
- An infant diagnosed with anorectal malformation should undergo renal ultrasonography as well as VCUG because of the high risk of associated genitourinary anomalies.

Conditions of the Pelvis

Central Nervous System Insults

Conditions of the Brain (Tumors, Infarcts, Encephalopathies)

Conditions of the Spinal Cord

Neuromuscular dysfunction of the lower urinary tract (LUT) may be either congenital or acquired. The most common cause of congenital dysfunction encountered by the urologist is the condition of neural tube defect (NTD) (Box 142-1). Before 1960, the outcome of children with NTDs was poor, with less than 10% surviving infancy (Rinck et al, 1989). Improvements in neurosurgical and urologic care have resulted in a significant improvement in the survival rate such that by the mid 1990s, more than 85% of children survived infancy (Rinck et al, 1989). Survival has plateaued at this level (Kancherla et al, 2014). The most important intervention in this population was the institution of clean intermittent catheterization (CIC) for the prevention of upper urinary tract deterioration (Lapides et al, 1971). A longitudinal cohort study revealed that one third of children die before 5 years of age, and a further one quarter die before the age of 40 years (Oakeshott et al, 2010). The risk of death correlates with a higher level of neurologic deficit (Oakeshott et al, 2010). As these patients live longer, renal failure becomes an important cause of mortality and thus necessitates lifelong monitoring and management of the urinary tract in infancy (Singhal and Mathew, 1999; McDonnell and McCann, 2000; Mitchell, 2005). For children who survive, challenges persist for the achievement of bowel and bladder continence (Bomalaski et al, 1995; Metcalfe et al, 2011) and sexual function (Lassmann et al, 2007).

NEURAL TUBE DEFECTS

Epidemiology of Neural Tube Defects

The most common cause of neurogenic bladder dysfunction in children is abnormal development of the spinal canal and intervertebral spinal cord. See Figure 142-1 for an example of an open myelomeningocele (MMC). Formation of the spinal cord and vertebral column begins at about the 18th day of gestation. Closure of the canal proceeds in a caudal direction from the cephalad end and is complete by 35 days. The exact mechanism that results in closure and what produces a dysraphic state have yet to be elucidated, but numerous factors have been implicated. NTDs have a worldwide incidence of 0.3 to 4.5 per 1000 births (de Jong et al, 2008). Based on data from 2004 to 2006, the estimated national prevalence of spina bifida (SB) (without encephalocele) in the United States when adjusted for maternal race and ethnicity is 3.50 per 10,000 live births (Parker et al, 2010). This correlates to an estimated 1460 cases annually (Parker et al, 2010). Children born to women of

Hispanic descent have the highest likelihood of an NTD (4.17 per 10,000 births). Non-Hispanic white children have a risk of 3.22 per 10,000 births. The risk for children of non-Hispanic black or African-American descent is the lowest at 2.64 per 10,000 births (Boulet et al, 2008). There is geographic and temporal variation in the incidence of NTDs (Olney and Mulinare, 1998, 2002).

Women with low levels of folic acid and impairment of folate-mediated pathways or antibodies to folate are known to be at increased risk of NTDs (Botto and Mulinare, 1999). Folic acid supplementation in prospective randomized trials resulted in a 50% to 70% decrease in the prevalence of NTDs (Prevention of neural tube defects, 1991; Czeizel and Dudás, 1992; Botto and Mulinare, 1999). In 1992 the U.S. Public Health Service recommended that women of childbearing age take a folic acid supplement (400 µg daily) (Recommendations for the use of folic acid, 1992). The neural tube develops early in gestation, before most women realize that they are pregnant (Botto and Mulinare, 1999). Thus, it is suggested that the optimal time for folic acid supplementation is at least 4 weeks before and during the first month of pregnancy (Czeizel and Dudás, 1992; Dawson et al, 2001). However, only one third of women take a folic acid supplement as recommended (Honein et al, 2001). Therefore, governments regulated the fortification of flour and pasta with folic acid in the late 1990s (Food and Drug Regulations, 1998). Fortification of grains with folic acid has resulted in a 20% to 50% decrease in the prevalence of NTDs (Honein et al, 2001; Godwin et al, 2008).

Risk Factors for the Development of Neural Tube Defects

There is a strong familial risk for NTDs. A mother with one affected child has a 20 to 50 times increased risk of having another child with an NTD, and for an individual with myelodysplasia the risk is 40 times greater than for normal individuals (Scarff and Fronczak, 1981; Stein et al, 1982).

Other well-documented risk factors include young and advanced maternal age (Vieira and Castillo Taucher, 2005); maternal obesity (Stothard et al, 2009); maternal diabetes (Soler et al, 1976); maternal fever or flu (Lynberg et al, 1994); maternal caffeine consumption (Schmidt et al, 2009); specific maternal occupational exposures (Blanco Muñoz et al, 2005); maternal low educational level and socioeconomic status (Blanco Muñoz et al, 2005); maternal passive smoking (Wang et al, 2013); maternal periconceptual stressful event (Li et al, 2013); low maternal weight gain (Shaw et al, 2001);

maternal use of folic acid antagonists such as valproic acid and/or carbamazepine (Lammer et al, 1987; Hernández-Díaz et al, 2001); preceding history of maternal miscarriage (Blanco Muñoz et al, 2006) or other birth defect (Yin et al, 2010); and higher birth order (Vieira, 2004).

Owing to the complex needs of these patients with neurologic, musculoskeletal, gastrointestinal, and developmental challenges, their care is best managed by a dedicated multidisciplinary team.

Pathogenesis

Almost all infants born with MMC have the Arnold-Chiari malformation, which includes hindbrain herniation, brainstem abnor-

malities, low-lying venous sinuses, and a small posterior fossa (Adzick et al, 2011). This malformation is also associated with hydrocephalus and developmental brain abnormalities (Adzick et al, 2011). This affects motor, cranial nerve, and cognitive functioning. Hydrocephalus has traditionally been managed by diverting cerebral spinal fluid to the peritoneal cavity with a surgically placed shunt (Adzick et al, 2011). Endoscopic third ventriculostomy combined with choroid plexus cauterization effectively manages hydrocephalus in more than 70% of patients with MMC, avoids the need for placement of a ventriculoperitoneal (VP) shunt, and has similar neurocognitive outcomes as the VP shunt (Warf and Campbell, 2008; Warf et al, 2009).

The neurologic lesion produced by the MMC can be variable, depending on what neural elements, if any, have everted with the meningocele sac. The bony vertebral level often provides little or no clue to the exact neurologic level or lesion produced. The height of the bony level may differ from the highest extent of the neurologic lesion for one to three vertebrae in either direction (Bauer et al, 1977). Therefore, the neurologic lesion produced by this condition influences LUT function in a variety of ways and cannot be predicted just by looking at the spinal abnormality or the neurologic function of the lower extremities. Table 142-1 notes the distribution of spinal levels affected in MMC.

Perinatal Concerns

Antenatal ultrasonography suggests that the insult to the central and peripheral nervous systems of a fetus with MMC is progressive, such that lower limb movement may be lost and hindbrain herniation and hydrocephalus may worsen during gestation (Korenromp et al, 1986; Sival et al, 1997). Animal studies have demonstrated that prenatal coverage of SB-like lesions can preserve neurologic function and limit hindbrain herniation (Meuli et al, 1995). It is postulated that the ultimate neurologic deficit in SB is the result of two “hits”: (1) the initial failure of neural tube formation and (2) ongoing injury to the exposed neural tissue in the intrauterine environment that results from mechanical and chemical trauma (Meuli et al, 1995; Adzick et al, 2011). Thus, it is suggested that in utero intervention may improve outcomes for children with SB.

To further evaluate this theory, a randomized trial of prenatal surgery before 26 weeks of gestation or standard postnatal repair of MMC, the Management of Myelomeningocele Study (MOMS), was completed. The primary outcome (a composite of fetal or neonatal death or the need for a cerebrospinal fluid shunt) was reduced in the prenatal surgery group (relative risk of 0.70). However, 40% of the prenatal closure group still required shunting, and not all experienced improved neuromotor function or complete resolution of hindbrain herniation. The second primary outcome (a composite score of mental development and motor function at 30 months) was also better in the prenatally treated group. No maternal deaths were noted. Fetal and neonatal deaths did not differ between the two groups. However, pregnancy complications, including oligohydramnios, chorioamniotic separation, placental abruption, need for transfusion at the time of delivery, and spontaneous membrane rupture, were more common in the prenatal group. One third of women with prenatal surgery had an area of dehiscence or a very thin uterine surgical scar at the time of delivery. Those fetuses that underwent prenatal surgery were much more likely to be preterm, with an average gestational age of 34.1 weeks (with 13% delivered

before 30 weeks) compared with 37.3 weeks of gestation in the postnatal surgery group (with none delivered before 30 weeks). In addition, infants in the prenatal surgery group underwent more procedures for delayed spinal cord tethering and had a much higher rate of respiratory distress syndrome and a lower birth weight (Adzick et al, 2011).

Bladder Function after Prenatal Closure of Myelomeningocele

Several early studies of a small number of children who underwent closure of the NTD in utero found that urodynamic parameters were similar to those published in the literature for children undergoing standard postnatal closure (Holzbeierlein et al, 2000; Holmes et al, 2001). A case-control series found that those with prenatal closure had a higher incidence of complete denervation of the external urinary sphincter and detrusor overactivity compared with those with postnatal closure (Koh et al, 2006). Larger studies with a comparative postnatal closure group confirmed that there is no difference in the need for CIC, bladder capacity, detrusor overactivity (Clayton et al, 2011; Lee et al, 2012b), incontinence between catheterizations, antimuscarinic use, antibiotic use, detrusor-sphincter dyssynergia (DSD) (Lee et al, 2012b), incidence of detrusor leak point pressure exceeding 40 cm H₂O, vesicoureteral reflux (VUR), need for a bowel regimen, or need for surgery including augmentation cystoplasty, catheterizable channel, or Malone antegrade continence procedure (Clayton et al, 2011).

In summary, prenatal closure of MMC appears to improve neuromotor function and decrease the need for ventriculo-peritoneal shunting. However, this advantage comes with an increased risk of maternal morbidity and preterm labor with its resultant complications. In addition, there is clear evidence that bowel and bladder function are not improved and in some cases may be hindered with prenatal closure of MMC when compared with postnatal closure.

Initial Postnatal Management

Ideally, it would be best to perform urodynamic testing immediately after the infant is born, but the risk of spinal infection and the need for prompt spinal closure have not made this a viable option. It was accomplished in one study, however, and the results showed that 1 in 30 children (3.3%) experienced a change in neurologic status as a result of the spinal canal closure (Kroovand et al, 1990). Therefore, **renal ultrasonography and measurement of residual urine are performed as early as possible after birth**, either before or immediately after the spinal defect is closed. Residual urine may be measured by ultrasound or catheterization after the child voids or leaks urine with a Valsalva maneuver (Bauer et al, 2012). Urodynamic studies are delayed until it is safe to transport the child to the urodynamic suite and place him or her on the back or side for the test. If the infant cannot empty the bladder after a spontaneous void, CIC is begun even before urodynamic studies are conducted. The normal bladder capacity in the newborn period is 10 to 15 mL; therefore a residual urine volume of less than 5 mL is acceptable. Other tests that should be performed in the neonatal period include urinalysis and culture, serum creatinine determination (if indicated after the first week of life when it reflects the child's renal function) (Bauer et al, 2012), and a careful neurologic examination of the lower extremities.

Once the spinal closure has healed sufficiently, a renal ultrasonogram is performed to assess upper urinary tract architecture and function. If hydronephrosis, ureteral dilation, renal size or contour discrepancy, or increased bladder wall thickness is noted, a voiding cystourethrogram (VCUG) is recommended (Bauer et al, 2012). Abnormalities on the initial urodynamic study that warrant further investigation with a VCUG include detrusor overactivity, poor compliance, elevated leak point pressure, or DSD (Bauer et al, 2012). **These studies meet several objectives: They provide baseline information about the radiologic appearance of the upper urinary tract and LUT as well as the condition of the sacral spinal cord and the central nervous system (CNS); they provide infor-**

mation that can be compared with findings of subsequent assessments, so that early signs of deterioration of urinary tract function and drainage, or of progressive neurologic denervation, can be detected; they help to identify infants at risk for urinary tract deterioration as a result of a poorly compliant or overactive detrusor or outflow obstruction from DSD, which predetermines the need to initiate prophylactic measures before any deterioration in upper urinary tract architecture and function actually takes place; and they help the physician to counsel parents about the child's future bladder and sexual function (McGuire et al, 1981; Bauer, 1984a, 1984b; Sidi et al, 1986; Lais et al, 1993). If an abnormality is detected on renal ultrasonography or VUR is demonstrated, a dimercaptosuccinic acid (DMSA) renal scan is recommended.

KEY POINTS: EVALUATION OF THE NEWBORN WITH NEUROGENIC BLADDER DYSFUNCTION

- Renal ultrasonography and measurement of residual urine are performed as early as possible after birth.
- Initial evaluation can be compared with findings on subsequent assessments, so that early signs of deterioration of urinary tract function and drainage, or of progressive neurologic denervation, can be detected.
- Infants at risk for urinary tract deterioration as a result of a poorly compliant or overactive detrusor or outflow obstruction from DSD need to be identified.
- This determines the need to initiate prophylactic measures before any deterioration in upper urinary tract architecture and function take place.
- Three categories of LUT dynamics may be detected: synergic (26%), dyssynergic with and without poor detrusor compliance (37%), and complete denervation (36%).

Findings

Five percent to 10% of newborns have an abnormal urinary tract on radiologic examination when first evaluated (Bauer, 1985); 3% have hydronephrosis secondary to spinal shock, probably from the spinal canal closure (Chiaramonte et al, 1986), and 15% have abnormalities that developed in utero as a result of abnormal LUT function in the form of outlet obstruction (Bauer, 2003).

Urodynamic studies in the newborn period have shown that 63% of infants have bladder contractions. This is also true for an equivalent number of children with upper lumbar or thoracic lesions in whom the sacral spinal cord is spared, 50% of whom have detrusor overactivity (Pontari et al, 1995). Thirty-seven percent have an acontractile detrusor with compliance during filling that is either good (20%) or poor (17%) in this subgroup (Bauer et al, 1984; Bauer, 2003). Electromyographic assessment of the external urethral sphincter demonstrates an intact sacral reflex arc with no evidence of lower motor neuron denervation in 40% of newborns; partial denervation is seen in 24%; and complete loss of sacral cord function is noted in 36% (Lais et al, 1993; Bauer, 2003).

Prediction of Risk of Upper Urinary Tract Deterioration

A combination of bladder contractility and external sphincter activity results in **three categories of LUT dynamics: synergic (26%), dyssynergic with and without poor detrusor compliance (37%), and complete denervation (36%) (Figs. 142-2 and 142-3) (Sidi et al, 1986; Bauer, 2003).** DSD occurs when the external sphincter fails to decrease or actually increases its activity during a detrusor contraction or a sustained increase in intravesical pressure as the bladder is filled to capacity (Blaivas et al, 1981). Frequently, a poorly compliant bladder with high intravesical pressure occurs in conjunction with a dyssynergic sphincter, resulting in a bladder that empties only at high intravesical pressure (Sidi et al, 1986).

Figure 142-2. Urinary tract deterioration is related to outflow obstruction and is most often associated with dyssynergy. Children with synergy converted to dyssynergy, and patients with complete denervation developed fibrosis with a fixed high outlet resistance in the external sphincter, before any changes occurred in the urinary tract. (From Bauer SB. Early evaluation and management of children with spina bifida. In: King LR, editor. Urologic surgery in neonates and young infants. Philadelphia: Saunders; 1988. p. 252–64.)

(Fig. 142-4). Synergy is characterized by complete silencing of the sphincter during a detrusor contraction or when capacity is reached at the end of filling. Voiding pressures are usually within the normal range. Complete denervation is noted when no bioelectric potentials are detectable in the region of the external sphincter at any time during the micturition cycle or in response to sacral stimulation or a Credé maneuver.

Categorizing LUT function in this way has been extremely useful because it reveals which children are at risk for urinary tract changes, which should be treated prophylactically, and which need close surveillance. Within the first 3 years of life, 71% of newborns with DSD had urinary tract deterioration on initial assessment or subsequent studies, whereas only 17% of synergic children and 23% of completely denervated individuals developed similar changes (see Fig. 142-2). Infants in the synergic group who showed deterioration did so only after they converted to a dyssynergic pattern of sphincter function. Among the infants with complete denervation, the ones who showed deterioration were those who had increased levels of urethral resistance, presumably caused by fibrosis of the skeletal muscle component of the external sphincter. Therefore it appears that bladder outlet obstruction is a major contributor to the development of urinary tract deterioration in these children. Poor detrusor compliance plays an important role in this regard, especially when outlet resistance exceeds 40 cm H₂O (McGuire et al, 1981; Landau et al, 1994; Tanaka et al, 1999). Detrusor compliance seems to be worse in children with high levels of outlet resistance (Ghoniem et al, 1989).

It may be that detrusor filling pressures need to be looked at in a more critical way to determine whether they are an important factor in upper urinary tract deterioration. Landau and colleagues developed the concept of low detrusor filling pressure (less than 30 cm H₂O) at specific volumes adjusted for age, and not at maximal capacity (Landau et al, 1994). Applying this idea, they noted significantly improved sensitivity in predicting upper urinary tract deterioration.

Early Intervention in Children with Myelodysplasia

The concept of early intervention for children with DSD, poor compliance, high bladder pressures, and outflow obstruction was introduced in the early 1990s (McGuire et al, 1981; Bauer et al, 1984; Sidi et al, 1986). Early intervention is herein defined as CIC

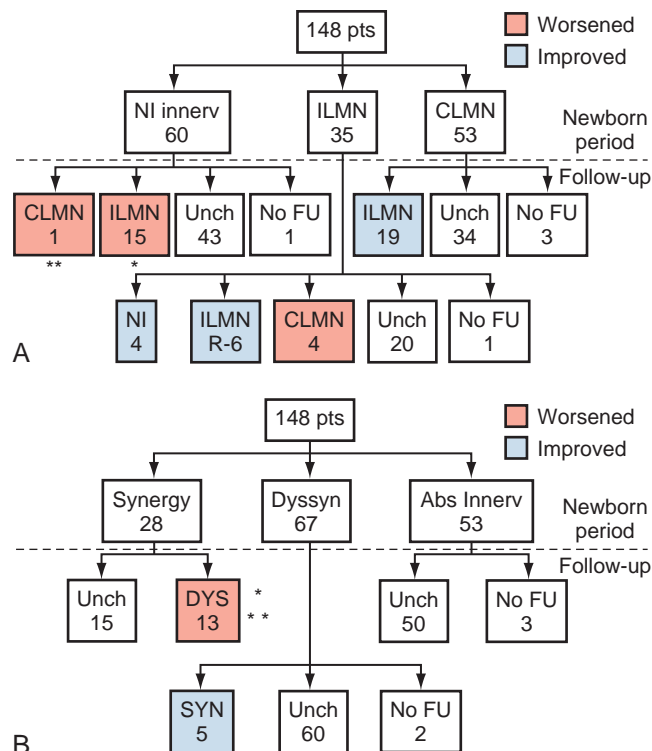

Figure 142-3. Changes in innervation of the purely sacral (A) and pontine-sacral (B) reflex arc pathways that occurred in a group of children with myelodysplasia who were monitored with sequential urodynamic studies beginning in the newborn period. A, The double asterisk indicates 1 patient changed from synergy to dyssynergy, and the single asterisk indicates 4 of 15 patients so changed. B, The single asterisk indicates 1 patient changed from normal to partial and then complete denervation, and the double asterisk indicates 4 patients changed from normal to partial denervation. CLMN, complete lower motor neuron lesion; DYS, dyssynergy; FU, follow-up; ILMN, incomplete lower motor neuron lesion; NI, normal innervation; SYN, synergy; Unch, unchanged. (From Lais A, Kasabian NG, Dyro FM, et al. Neurosurgical implications of continuous neuro-urological surveillance of children with myelodysplasia. J Urol 1993;150: 1879–83.)

and antimuscarinic therapy. There has been some controversy about the benefit of early intervention in children with myelodysplasia; however, there is a plethora of data that document its beneficial effects on outcomes in this population.

Effect of Early Intervention on Bladder Function

In one study of 26 newborns with DSD and high bladder pressures treated with CIC and oxybutynin, this drug was noted to eliminate overactive contractions in 2 of 14 children and lowered peak contractile pressure in the remaining 12 children (Fig. 142-5). It was also noted to lower bladder filling pressure at capacity in all 12 patients with poor compliance (Kasabian et al, 1992). Minimal side effects were noted from its use, and none from CIC (Kasabian et al, 1992). Early intervention also results in improved continence (Kaefer et al, 1999). One study found that up to 44% of children treated with early intervention were dry at age 6 years (Dik et al, 2006).

Early Initiation of Clean Intermittent Catheterization Decreases the Rate of Urinary Tract Infection

Studies of expectant management document urinary tract infection (UTI) in 50% of children by the age of 15 months and 81% by the

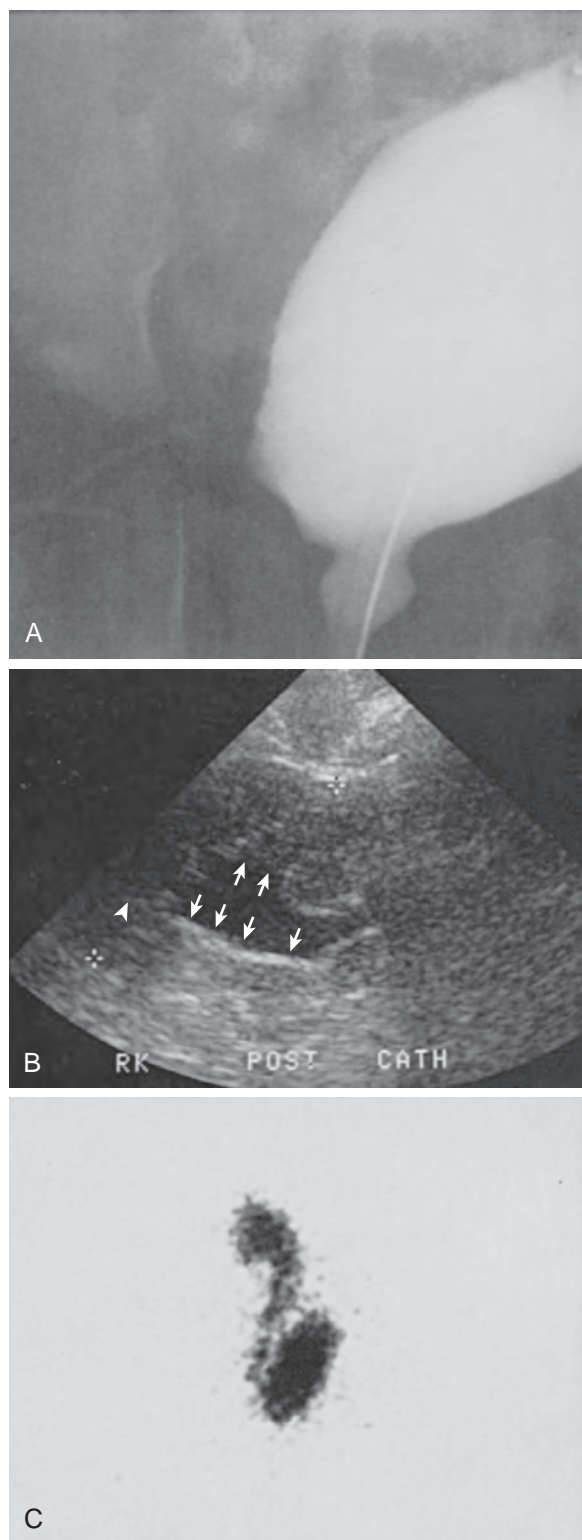

Figure 142-4. A, A voiding cystourethrogram in a female neonate with dyssynergy and elevated voiding pressures demonstrates no reflux and a smooth-walled bladder. Her initial renal echogram was normal. She was started on clean intermittent catheterization and oxybutynin chloride (Ditropan) but did not respond. Within 1 year she developed right hydronephrosis (B, arrows) and severe reflux, evident on a radionuclide cystogram (C).

Figure 142-5. Oxybutynin is a potent anticholinergic agent that dramatically delays detrusor contractions and lowers contraction pressure, as demonstrated on these two graphs. U.C., uninhibited contraction.

age of 15 years. In addition, recurrent UTIs are common, with over 44% of children having 5 episodes and almost 10% having more than 20 episodes of UTI (Filler et al, 2011), whereas in children with early institution of CIC, the mean number of infections is 0.3 per year (Wide et al, 2012). Several studies have demonstrated a decreased rate of UTI when CIC is used, either within the same patient (Olandoski et al, 2011) or in contrast to a comparative group (Kari et al, 2009).

Early Intervention Decreases Upper Urinary Tract Deterioration

The potential for the development of hydroureteronephrosis in children with high-risk bladders including DSD is well established. In one study, 72% of children with dyssynergia later developed hydronephrosis (Bauer et al, 1984). Other studies note hydroureteronephrosis in children with high-risk bladders treated expectantly in 18% to 80% (Geraniotis et al, 1988; Edelstein et al, 1995; Kaefer et al, 1999; Kochakarn et al, 2004). The development of hydroureteronephrosis is much less common in trials of early intervention, ranging from 0% to 15% (Geraniotis et al, 1988; Edelstein et al, 1995; Kaefer et al, 1999; Dik et al, 2006).

Early Intervention Reduces Rate of Vesicoureteral Reflux

Studies of expectant management of children with myelodysplasia and high-risk bladders identify VUR in up to 50% of patients by the age of 9 years (Filler et al, 2011). In children managed with CIC from birth, the development of VUR is much less common (28%) (Wide et al, 2012). Another study also found that children treated with CIC early had a much lower incidence of VUR than those who were not on therapy or were noncompliant with therapy (62% vs. 92%) (Kari et al, 2009).

Early Intervention Decreases the Need for Surgery

Several studies comparing early intervention with expectant therapy have noted a lower need for surgical intervention in children with high-risk bladders. Up to 11% of children treated expectantly may require urinary diversion (Filler et al, 2011). Comparatively, no children required renal protective surgery in a group of 41 children treated with early intervention. In fact, only 1 child in this group required surgery for incontinence, and 6 received injection of botulinum toxin (Wide et al, 2012). Others have documented an 18% to 24% reduction in the need for bladder augmentation when early

intervention is compared with expectant management (Kaefer et al, 1999; Kochakarn et al, 2004).

Early Intervention Decreases the Incidence of Renal Scarring and End-Stage Renal Disease

Early intervention does not appear to be advantageous for children who can empty their bladder spontaneously (Torre et al, 2011). Studies of historical cohorts document evidence of renal scarring in 27% to 50% of children (Lewis et al, 1994; Müller et al, 2002; Filler et al, 2011). The rate of renal scarring in children treated with early intervention is much lower, ranging from 4% to 12% (Dik et al, 2006; Torre et al, 2011; Wide et al, 2012). As anticipated, the decrease in renal scarring related to a decreased incidence of end-stage renal disease (ESRD) in children treated with early intervention (0% to 1.6%) (Dik et al, 2006; Torre et al, 2011; Malakounides et al, 2013) compared with those managed expectantly (30%) (Rickwood et al, 1984).

Assessment of Renal Function in Children with Neuromuscular Dysfunction of the Lower Urinary Tract

Although serum creatinine is a widely used marker of glomerular filtration rate (GFR), it is known to be a poor marker of renal function in children with neurogenic bladder dysfunction. Creatinine is produced from the nonenzymatic degradation of creatinine derived from muscle. It is freely filtered and secreted by the kidney (Perrone, 1992). Its serum level is dependent on age, gender, height, and muscle mass (Pham-Huy et al, 2003). Individuals with reduced muscle mass may demonstrate a low endogenous creatinine release that may not result in an elevated creatinine level despite a decrease in GFR (Quan et al, 1997). Numerous studies have confirmed that serum creatinine is not an accurate reflection of GFR in children with myelodysplasia, who often have diminished muscle mass (Quan, 1997; Filler and Lepage, 2003; Pham-Huy et al, 2003). **The gold standard for measuring GFR is the renal scan, which is invasive and exposes the patient to radiation.** Thus, it is preferable to have a serum marker that would closely reflect GFR in this specific population, at high risk of renal functional impairment.

Small molecular weight proteins, such as cystatin C, have been suggested as alternative markers of GFR for children with neuromuscular dysfunction of the urinary tract (Pham-Huy et al, 2003). Cystatin C is a 13-kDa cysteine proteinase inhibitor, produced at a constant rate by all nucleated cells. It is freely filtered by the glomerulus, not secreted from the renal tubule, and almost entirely catabolized at the proximal tubule (Grubb, 2000). Thus, the serum concentration of cystatin C is determined primarily by glomerular filtration. When compared with commonly accepted gold standards for the measurement of GFR in children with SB, serum cystatin C levels correlate more closely with GFR than when estimated by the Schwarz formula or other low-molecular-weight proteins (Pham-Huy et al, 2003; Abrahamsson et al, 2008). However, at early stages of renal functional impairment, cystatin C may not be as reliable as a full clearance study (Filler and Lepage, 2003; Abrahamsson et al, 2008). A formula for estimating GFR from serum creatinine in children has been proposed, $\log(\text{GFR}) = 1.962 + [1.123 \times \log(1/\text{cystatin C})]$ (Filler and Lepage, 2003). A recent meta-analysis in a diverse population of adults revealed that cystatin C more accurately predicts the risk of ESRD and death than creatinine (Shlipak et al, 2013).

Thus, serum cystatin C is superior to serum creatinine for estimating GFR in this population; however, when mild renal functional impairment is suspected, a full nuclear medicine clearance study may be required.

Kidney Size in Children with Spina Bifida

Sutherland and colleagues (1997) noted that children with SB had smaller kidneys than their normal peers and generated a nomogram for renal size in this population. The finding of small renal size in

some children with SB has been confirmed by others (Del Gado et al, 2003; Montaldo et al, 2014). It was initially suggested that a potential cause could be low levels of growth hormone, but this has been excluded by the demonstration of normal levels of insulin-like growth factor-1 (Del Gado et al, 2003; Montaldo et al, 2014). A study of newborns with SB found those with small kidneys as well as their mothers to have high serum levels of homocysteine. These infants also had a higher incidence of intrauterine growth retardation. As hyperhomocysteinemia has been linked to placental vasculopathy, it has been suggested that the mechanism for small renal size in children with SB might be related to abnormal placental function (Montaldo et al, 2014). Small renal size in children with SB has been associated with decreased renal function (Del Gado et al, 2003).

Renal Dysfunction in Myelodysplasia

Several studies have identified that surrogate markers of renal dysfunction in children with SB are frequently abnormal. For example, 54% and 19% of children referred to nephrologists for recurrent UTI were noted to have microalbuminuria and metabolic acidosis, respectively (Olandoski et al, 2011). The rate of hypertension in myelodysplastic children ranges from 12% to 41% (Rickwood et al, 1984; Mazur et al, 2011; Olandoski et al, 2011). This is significantly higher than national age-matched control groups (3%) (Mazur et al, 2011). The risk of hypertension is positively correlated with maximum body mass index (Mazur et al, 2011). Hypertension is more frequently noted after puberty and in those with renal scarring (Rickwood et al, 1984).

Some degree of renal dysfunction has been noted in 30% to 50% of children with SB (Müller et al, 2002; Malakounides et al, 2013). Historical studies noted an incidence of ESRD in 18% of children before and 30% of children after puberty (Rickwood et al, 1984). Others have found that ESRD is noted in 15% of those with SB (Cy, 2010). More contemporary studies assessing early intervention with CIC and antimuscarinics note much lower rates of renal dysfunction (6%) and ESRD (0% to 1.6%) (Dik et al, 2006; Torre et al, 2011; Malakounides et al, 2013).

Determinants of Risk of Renal Dysfunction in Myelodysplasia. There has been much investigation regarding the determinants of renal functional loss in children with myelodysplasia. In most studies, renal deterioration or dysfunction is defined as altered renal function as measured by creatinine or creatinine clearance or renal scarring noted on DMSA renal scans. Urodynamic findings that are associated with increased incidence of renal deterioration such as hydronephrosis, VUR, and renal scarring include DSD (Bauer et al, 1984; Ozel et al, 2007); high detrusor pressures (Arora et al, 2007; Ozel et al, 2007; Wide et al, 2012); and detrusor overactivity (Ozel et al, 2007). The association between history of febrile UTI and renal scarring in this population is well documented (Ozel et al, 2007; Shiroyanagi et al, 2009). Hydronephrosis (Arora et al, 2007; DeLair et al, 2007; Ozel et al, 2007; Torre et al, 2011) and VUR (Arora et al, 2007; DeLair et al, 2007; Ozel et al, 2007; Torre et al, 2011) are also associated with renal scarring, although one study using a multivariate analysis demonstrated that a high-pressure bladder and hydronephrosis, in the absence of VUR, were not associated with renal cortical loss (DeLair et al, 2007). Lack of compliance with recommended therapy has also been shown to be an important factor in the development of renal scarring in this population (Kari et al, 2009; Wide et al, 2012).

Sexual Function

Sexuality in this population is becoming an increasingly important issue as more individuals reach adulthood and want to marry or to have intimate relationships (Cromer et al, 1990). Many psychosocial factors play a role in the development and sexual maturation of children with SB. Parents and health care workers are often reluctant to discuss sexual development with adolescents (Sandler et al, 1996; Joyner et al, 1998; Woodhouse, 1998). In addition, teens with SB often experience social isolation (Dorner, 1977;

KEY POINTS: EARLY INTERVENTION AND RENAL FUNCTION IN NEURAL TUBE DEFECTS

- Early intervention with CIC and antimuscarinics improves urodynamic parameters and decreases the rate of UTI, VUR, upper urinary tract deterioration, and the incidence of ESRD.
- Cystatin C is superior to serum creatinine to monitor renal function in children with NTDs. Renography is the gold standard for estimating GFR.
- Determinants of risk of renal dysfunction in myelodysplasia include DSD, high detrusor pressures, detrusor overactivity, febrile UTIs, and VUR. These entities should be actively managed to minimize risk of renal functional decline.

Joyner et al, 1998). This is supported by studies showing that children with MMC are less likely than those without MMC to have their peers act as the main source of sexual education (Dorner, 1977; Decter et al, 1997). Some children with MMC are dependent on others for their activities of daily living and therefore often live with their parents or an alternative caregiver (Börjeson and Lagergren, 1990). Young men with MMC reported better erectile function and intercourse satisfaction when they lived independently (Gamé et al, 2006). Parents of children with SB tend to be more overprotective than parents of normal children and are less willing to grant autonomy to them for adequate peer and sexual development (Holmbeck et al, 2002). When asked about sexual function, many teens with MMC report they find their parents are overprotective or too restrictive (Dorner, 1977). Parental permissiveness in social participation and age-appropriate treatment by parents contribute positively to high self-esteem in these adolescents (Wolman et al, 1994). In a study of life satisfaction of Dutch young adults with SB, the highest proportion of dissatisfaction was found for partnership relations (49%) and sex life (55%). More than 50% of young adults with SB report that they are dissatisfied with their current sex life (Verhoef et al, 2005a). Males with SB were much more dissatisfied with their sex life than females (Barf et al, 2007).

Boys reach puberty at an age similar to the age for normal males, whereas breast development and menarche tend to start as much as 2 years earlier than usual in myelodysplastic females compared with normal girls. In 15% of girls with myelodysplasia, the average age at menarche varies from 10.9 to 11.4 years (Trollman et al, 1998). The cause of this early hormonal surge is uncertain, but it may be related to changes in pituitary function in girls secondary to hydrocephalus (Hayden et al, 1979).

Sexual education specific to individuals with SB should be provided. Latex-free condoms are necessary for those with latex allergy or those adhering to latex avoidance recommendations. The use of estrogen and progestin contraceptives may increase the risk of thromboembolic events in those with decreased mobility, and the use of intrauterine devices for contraception is unsafe owing to pelvic infections (Jackson and Mott, 2007).

The degree of sexuality is inversely proportional to the level of neurologic dysfunction (Joyner et al, 1998; Palmer et al, 1999; Gatti et al, 2009). In addition, lower occurrence of sexual activity seemed to be noted in populations with greater rates of incontinence and more severe disability (Börjeson and Lagergren, 1990; Sandler et al, 1996; Verhoef et al, 2005a; Cardenas et al, 2008; Gatti et al, 2009). Those with the lowest lesion levels are most likely to form partnerships (Gatti et al, 2009). Increasing age is associated with increased likelihood of having a partner; those older than 26 years were 2.1 times more likely to have a partner than those aged 18 to 25 years (Gatti et al, 2009). The absence of hydrocephalus is a positive predictor of sexual activity (Verhoef et al, 2005a). This effect is more pronounced for women than for men (Cardenas et al, 2008). Females are more likely than males to be sexually active (Sawyer and Roberts, 1999; Verhoef et al, 2005a; Cardenas et al, 2008). **Females with SB are at risk of sexual abuse.** Unwanted sexual attention was reported by 37% and unwanted sexual

touching was noted by 30% of women with SB in one study (Sawyer and Roberts, 1999). Four percent of men with SB have experienced improper sexual touching (Sawyer and Roberts, 1999).

In several studies, researchers interviewed groups of teenagers with MMC and reported that 28% to 40% of them had had one or more sexual encounters and almost all of them had a desire to marry and ultimately to bear children (Cromer et al, 1990; Palmer et al, 1999). Seventy percent of those with SB desired sexual contact (Verhoef et al, 2005a). Common features of studies evaluating sexual function in adolescents and young people with MMC include low participation rates resulting from patient or parental refusal and elimination of patients with severe physical disabilities and/or severely compromised intellectual function. This results in a very selected population in which only highly functioning individuals are studied. Five of six studies found that more than 70% of young men with MMC are able to obtain an erection (range 70% to 92%) (Cass et al, 1986; Diamond et al, 1986; Börjeson and Lagergren, 1990; Sandler et al, 1996; Decter et al, 1997). The ability to ejaculate has been found to range from approximately 40% to 75% (Cass et al, 1986; Börjeson and Lagergren, 1990; Sandler et al, 1996; Decter et al, 1997). In some cases, retrograde ejaculation was noted (Sandler et al, 1996). Self-report of sexual activity varied greatly with different study populations, ranging from 8% to 83% for males (Laurence and Beresford, 1975; Cass et al, 1986; Börjeson and Lagergren, 1990; Sandler et al, 1996; Decter et al, 1997) and 23% to 69% for females (Cass et al, 1986; Börjeson and Lagergren, 1990).

Studies reveal that 70% to 80% of myelodysplastic women were able to become pregnant and to have an uneventful pregnancy and delivery, although urinary incontinence in the latter stages of gestation was common in many, as was delivery by cesarean section (Laurence and Beresford, 1975; Cass et al, 1986; Bomalaski et al, 1995; Arata et al, 2000). In the same studies, 17% to 39% of male subjects claimed that they were able to father children, and another 25% had a good prognosis for fathering them (Laurence and Beresford, 1975; Bomalaski et al, 1995; Decter et al, 1997). Both females and males with SB have an increased risk of having a child with SB, compared with individuals without SB (3.7% incidence of SB in offspring) (Bong and Royner, 2007). This effect is more pronounced in females (Chatkupt et al, 1992). If both parents have SB, the risk of having a child with SB increases to 15% (Cameron and Moran, 2009). To reduce this risk, women with SB should be counseled about taking 4.0 to 5.0 mg of folic acid supplement daily before even contemplating getting pregnant (Visconti et al, 2012). It is more likely that men will have problems with erectile and ejaculatory function because the sacral spinal cord is frequently involved, whereas reproductive function in women, which is under hormonal control, is not affected. Men with neurologic lesions at S1 or lower are likely to have normal or adequate reproductive sexual function, but only 50% of those with lesions above that level have adequate function (Woodhouse, 1994, 2005). Poor semen quality (Reilly and Oates, 1992) and Sertoli cell-only histology on testis biopsy (Glass and Soni, 1999) have been reported as reasons (in addition to erectile dysfunction) for infertility in males with SB.

One study used a validated questionnaire, the International Index of Erectile Function (IIEF) to evaluate sexual function in men older than 18 years with MMC (Gamé et al, 2006). Overall, 75% of the men had erectile dysfunction. Of the 16 men who had recently had sexual intercourse, 4 had no erectile dysfunction, 3 had mild dysfunction, 4 had mild-to-moderate dysfunction, and 5 had severe dysfunction. Erectile function was directly related to the ability to maintain erections and the presence of a sacral nerve root lesion (Gamé et al, 2006). The role of intact pelvic parasympathetic reflex activity has been demonstrated to be a positive correlate in men with MMC (Diamond et al, 1986; Sandler et al, 1996).

Medical therapy for erectile dysfunction has been shown to be effective in this population. Sildenafil improved erectile function in 80% of men with MMC in a randomized, double-blind, placebo-controlled trial (Palmer et al, 1999). Some promise has been shown with attempts to restore penile sensation in men with SB by connecting the sensory ilioinguinal nerve

microsurgically to the ipsilateral dorsal nerve of the penis in men with normal groin sensation (Jacobs et al, 2013; Overgoor et al, 2013). Preliminary results in small case series showed increased sensation of the ipsilateral glans penis, better overall sexual function, and increased satisfaction (Overgoor et al, 2013), but these findings await long-term studies.

Management of Neurogenic Bowel Dysfunction in Myelomeningocele

Options for the management of constipation traditionally include dietary modification, digital stimulation, laxatives, enemas, and biofeedback therapy. Management in children with neurogenic bowel must be tailored to the individual's ability to address mobility and balance, ability for self-care, manual dexterity, and anal sphincter tone.

Two thirds of children aged 6 and older and one third of children and young adults aged 16 to 25 years with SB report fecal incontinence, which has a substantial impact on their quality of life (Krough et al, 2003; Verhoef, et al, 2005b). Most recommend a **graduated approach** to the management of constipation in this population (Vande Velde et al, 2007; Burgers et al, 2013; Choi et al, 2013a, 2013b). Initially, treatment is directed toward high dietary fiber and osmotic laxatives (Vande Velde et al, 2007; Choi et al, 2013b). Polyethylene glycol has been shown to be more effective in this population than lactulose (Rendeli et al, 2006). An option for those who are unable to sit on the toilet is **controlled constipation with manual evacuation of stool** because large-volume enemas cannot easily be delivered in these children (Vande Velde et al, 2007). In those who are able sit independently, with some anal sphincter activity, a regular postprandial toilet sitting regimen three times daily after meals has been effective, as it employs the gastrocolic reflex to initiate a bowel movement (Vande Velde et al, 2007). When continence is not achieved by defecation, **digital stimulation** is suggested (Vande Velde et al, 2007). If manual evacuation fails or if the anal sphincter is nonfunctioning, **retrograde enemas** (tap water with irrigation cone) followed by kneading of the abdomen or alternative transanal irrigation devices (Ausili et al, 2010) are instituted (Shandling and Gilmour, 1987; Vande Velde et al, 2007). Initially enemas are given daily, and, if successful, the frequency can be decreased to every second day. Initial enema volume is 500 mL and increased to 1 L if required. If fecal incontinence persists at this point, the **antegrade continence enema (ACE)** is considered the next step in management. Antegrade continent enemas are begun on a daily basis and reduced to 4 to 5 times per week as needed over time, if successful. Volumes used range from 1 to 2 L (Vande Velde et al, 2007). This stepwise approach to fecal pseudocontinence was successful in 69% of patients with MMC; 10% achieved fecal continence. Of those who were pseudocontinent, 16% used manual evacuation, 10% used a toileting scheme, 42% used retrograde enemas, and 32% used ACE (Vande Velde et al, 2007). The addition of polyethylene glycol (GoLYTELY), mineral oil, polyethylene glycol 3350 (MiraLAX), or glycerin to tap water enemas has successfully increased the continence rate for ACE regimens (Bani-Hani et al, 2008).

ACE delivered through a surgically placed appendicostomy or cecostomy was first described in children with SB or anorectal malformations by Malone and colleagues (1990). Use of ACE has been shown to significantly improve fecal continence, not increase the amount of time dedicated to bowel care, and improve quality of life (Ok and Kurzrock, 2011). Anal plugs may be effective for some patients during specific activities, such as swimming (Vande Velde et al, 2007). Long-term studies indicate that approximately 40% of children discontinue use of their surgically created cecostomies after a median of 11 years. Reasons for nonuse include lack of effectiveness, complications, psychological issues, and poor compliance (Yardley et al, 2009). In those who continue using the cecostomy, their level of satisfaction is very high (Yardley et al, 2009). Placement of percutaneous cecostomy under fluoroscopic guidance for delivery of the ACE in children with SB was described by Shandling

and colleagues (1996); it provides the advantage of avoiding laparotomy or laparoscopy.

Initial Diagnostic Evaluation and Follow-Up of Congenital Neuropathic Dysfunction in Children

The initial diagnostic evaluation of neuropathic bladder dysfunction will be discussed as it relates to specific pathologic processes throughout the chapter. The International Children's Continence Society (ICCS) has recently published general recommendations for the follow-up of congenital neuropathic bladder that are a compilation of best practices as a result of a paucity of high-level evidence (Bauer et al, 2012). These recommendations are based on developmental stages and associated growth spurts in the first 2 years of life and adolescence that may increase the risk of spinal cord tethering and are summarized in Table 142-2. An example of the magnetic resonance imaging (MRI) findings in a patient with spinal tethering is shown in Figure 142-6. A recent study has noted that in adulthood, patients followed at a multidisciplinary SB clinic had developed a urologic issue at a median of 12 months and 40% had an asymptomatic urologic issue at 36 months. This suggests that a follow-up period of 12 to 18 months in adulthood may be prudent (Duplisea et al, 2014).

PRINCIPLES OF MANAGEMENT OF NEUROMUSCULAR DYSFUNCTION OF THE LOWER URINARY TRACT

The primary principle in management of neuromuscular dysfunction of the LUT is preservation of renal function. Secondary goals include attaining urinary and fecal continence, avoidance of UTI, and facilitation of sexual function and fertility. **Preservation of renal function is best achieved by maintaining low bladder pressures, avoiding hydronephrosis, and actively managing VUR if recurrent UTIs occur.** Initial efforts to reduce bladder pressures include minimally invasive therapy to reduce bladder pressures such as CIC and antimuscarinic therapy. If this is unsuccessful, overnight indwelling catheter drainage has been shown to improve or resolve hydronephrosis, increase bladder capacity, and decrease the frequency of UTI (Koff et al, 2005). Those who have failed conservative management require surgical intervention. When choosing a surgical intervention, consideration must be given to the patient's ambulatory status, body habitus, manual dexterity, compliance with therapy, and capacity to provide self-care.

The normal bladder functions by storing urine at low pressures and empties by coordinating decreased outlet resistance with a bladder contraction. In neuropathic dysfunction, incontinence may result from failure of proper storage, emptying, or both. Storage may be compromised by low compliance, low capacity, overactive bladder contractions, and low bladder outlet resistance. Emptying may be compromised by inadequate bladder contractions or DSD. Tables 142-3 and 142-4 indicate some possible options to address the failure of storage (Table 142-3) and emptying (Table 142-4) in neuropathic dysfunction of the LUT in children. The specific medical and surgical treatment options are described in the following sections.

Medical Management of Neuropathic Dysfunction of the Lower Urinary Tract

Antimuscarinic drugs are the first-line treatment for detrusor overactivity (Hood and Andersson, 2013). The detrusor smooth muscle has M₂ and M₃ receptors. M₂'s predominate in number; however, M₃ receptors mediate the direct contractile effects of acetylcholine in the detrusor (Hegde and Eglen, 1999). Initial response rates are good; however, adverse effects and decreasing efficacy result in dwindling long-term compliance (Hood and Andersson, 2013). Use of antimuscarinics in children with detrusor overactivity results in increased bladder capacity, increased volume to first detrusor

TABLE 142-2 Summary of the International Children's Continence Society Recommendations for the Diagnostic Evaluation and Follow-up of Congenital Neuropathic Bladder and Bowel Dysfunction in Children

AGE GROUP	TYPE OF INVESTIGATION	RECOMMENDED FREQUENCY OF INVESTIGATION	INDICATION FOR INVESTIGATION
Newborn to toddler	Ultrasound Urodynamic studies DMSA renal scan	Every 6 mo until age 2 yr Every 12 mo When indicated	High risk of tethering with rapid growth UTIs or lower extremity changes Consider if VUR on initial VCUG/RNC or febrile UTIs
Toddler to adolescent	Ultrasound Urodynamic studies DMSA renal scan	Every 12 to 24 mo When indicated When indicated	Low risk of tethering with slower growth Change in ambulation or lower extremity function Febrile UTIs
Adolescent to adult	Ultrasound Urodynamic Studies VCUG/RNC	Every 12 mo When indicated When indicated	Low risk of tethering with slower growth; may decrease to every 24 mo once growth velocity has decreased Development of hydronephrosis, more frequent CIC required for continence, new wetting, recurrent UTI Recurrent UTI
Adult	Ultrasound Urodynamic studies	Every 36 mo When indicated	Low risk of tethering without ongoing somatic growth Development of hydronephrosis, more frequent CIC required for continence, new wetting, recurrent UTI

CIC, clean intermittent catheterization; DMSA, dimercaptosuccinic acid; RNC, radionuclide cystogram; UTI, urinary tract infection; VCUG, voiding cystourethrogram; VUR, vesicoureteral reflux.

KEY POINTS: MANAGEMENT OF NEUROPATHIC DYSFUNCTION OF THE LOWER URINARY TRACT

- The primary goal of management is preservation of renal function.
- Secondary goals of management include urinary and fecal continence, avoidance of UTI, and facilitation of sexual function and fertility.
- Preservation of renal function is achieved by maintaining low bladder pressures and active management of VUR and avoidance of UTI.
- The ICCS recommendations for follow-up are based on developmental stages and the relative risk for secondary spinal cord tethering.
- Minimally invasive therapies should precede the use of more invasive therapies to address failure of the bladder to store or empty.

contraction, decreased number of incontinence episodes, and decreased number of catheterizations (Ellsworth et al, 2005; Nijman et al, 2005; Christoph et al, 2007; Reddy et al, 2008; Alloussi et al, 2010; Bolduc et al, 2010). Common adverse events include dry mouth, constipation, blurred vision, facial flushing, dizziness, and headache (Ellsworth et al, 2005; Nijman et al, 2005; Christoph et al, 2007; Reddy et al, 2008; Alloussi et al, 2010; Bolduc et al, 2010). There have been some concerns about potential cognitive effects of antimuscarinics, but a prospective, randomized, double-blind trial showed no negative effect of antimuscarinic medications on attention or memory (Giramonti et al, 2008).

The most commonly used antimuscarinic agent in children is oxybutynin. It may be delivered orally, transcutaneously (Cartwright et al, 2009), or intravesically (Guerra et al, 2008). Oral administration is usually done at 0.2 mg/kg/dose given up to three times daily. Oral preparations include tablets, syrup, and extended-release tablets. All three have been shown to be safe and effective

Figure 142-6. Magnetic resonance image of a 9-year-old girl who developed a tethered cord after myelomeningocele repair reveals the conus opposite the L3-4 vertebrae (arrow).

TABLE 142-3 Strategies to Address Inadequate Bladder Storage in Children with Neurogenic Bladder Dysfunction

CAUSE OF INADEQUATE STORAGE	MINIMALLY INVASIVE TREATMENT OPTIONS	MORE INVASIVE TREATMENT OPTIONS
Low compliance	CIC Antimuscarinic therapy Overnight catheter drainage	Intravesical botulinum toxin Augmentation cystoplasty Urinary diversion
Low capacity	Antimuscarinic therapy Overnight catheter drainage	Intravesical botulinum toxin Augmentation cystoplasty Urinary diversion
Overactive bladder contractions	CIC Antimuscarinic therapy Overnight catheter drainage	Intravesical botulinum toxin Augmentation cystoplasty Urinary diversion
Low bladder outlet resistance	Sympathomimetic therapy	Bladder neck sling Bladder neck procedure Injection of bulking agents into bladder neck

CIC, clean intermittent catheterization.

TABLE 142-4 Strategies to Address Inadequate Bladder Emptying in Children with Neurogenic Bladder Dysfunction

CAUSE OF INADEQUATE EMPTYING	MINIMALLY INVASIVE TREATMENT OPTIONS	MORE INVASIVE TREATMENT OPTIONS
Inadequate bladder contractions	CIC Overnight catheter drainage	Neuromodulation
Detrusor sphincter dyssynergia	CIC Antimuscarinic therapy Overnight catheter drainage	Intravesical and/or sphincteric botulinum toxin Augmentation cystoplasty Urinary diversion Neuromodulation

CIC, clean intermittent catheterization.

in children (Franco et al, 2005). The transdermal dose is 3.9 mg daily (Cartwright et al, 2009). Transdermal oxybutynin has been shown to be a well-tolerated and effective alternative to oral oxybutynin in children with neurogenic detrusor overactivity. Skin irritation is noted in some patients, which leads to discontinuation of treatment in 20% of children (Cartwright et al, 2009; Gleason, et al, 2014). A systematic review noted a low level of evidence for the intravesical use of oxybutynin, which is thought to result in fewer side effects by avoiding first-pass metabolism. It did increase maximum bladder capacity and decrease bladder pressure with lower side effects than oral administration; however, 9% of children discontinued its use because of side effects and 22% because of other issues such as inconvenience of administration (i.e., crushing pills to prepare the solution) (Guerra et al, 2008).

Fesoterodine is an oral antimuscarinic. Its active metabolite, 5-hydroxymethyl tolteridene, is the same as tolteridene, but fesoterodine has less pharmacokinetic variability (Malhotra et al, 2011). It has been shown to be safe and tolerable in children at daily doses of 4 mg and 8 mg (Malhotra et al, 2012). Its main benefit is the fact that a methyl group has been added that bypasses the cytochrome oxidase enzymes that convert tolterodine to its active form, leading to a more effective antimuscarinic drug (Chapple et al, 2007).

Solifenacin is a once-daily antimuscarinic that has been shown to increase urodynamic bladder capacity, decrease overactive contractions, and improve continence with acceptable tolerability and safety in an open-label study of children with neurogenic and non-neurogenic detrusor overactivity who were recalcitrant to oxybutynin or tolterodine therapy (Bolduc et al, 2010). In this study, 21% had mild side effects, 4% had moderate side effects, and 5% withdrew because of intolerable adverse effects.

Tolteridene (antimuscarinic) has been noted to inhibit nonvoiding bladder activity, as well as to reduce the amplitude of voiding

contractions (Gillespie et al, 2012). In children with neurogenic detrusor overactivity, tolteridene was shown to be well tolerated, with minimal treatment-related adverse events; to increase functional bladder capacity in children younger than 10 years; and to decrease the mean number of incontinence episodes with long-term (12-month) use (Reddy et al, 2008).

Mirabegron is a novel β_3 -adrenergic receptor antagonist that decreases the number of micturitions and improves continence (Yamaguchi et al, 2014). It works by stimulating β_3 receptors located throughout the bladder that, when stimulated, elicit relaxation of the detrusor muscle by activating adenylyl cyclase, causing increases in the intracellular levels of cyclic adenosine monophosphate (cAMP) and calcium (Chapple et al, 2014). It is effective in adults but has not yet been approved by the U.S. Food and Drug Administration (FDA) for use in children.

Sympathomimetic Agents (Fig. 142-7)

Examples of sympathomimetic agents include ephedrine hydrochloride (0.5 to 1.0 mg/kg/day tid) and pseudoephedrine (0.4 mg/kg bid to 0.9 mg/kg tid). If incontinence results from inadequate urethral resistance, sympathomimetic agents act to increase tone at the bladder neck where the concentration of α -adrenergic receptors is highest, thereby raising outlet resistance and improving continence. It is hard to predict which children might respond to these drugs, which potentially increase bladder outlet resistance by stimulating receptors in the trigone and bladder neck, but in some patients there is a dramatic increase leading to continence between CICs (Bauer, personal communication, 2014). Regular use of sympathomimetic agents, however, may be limited by their side effects, including dizziness, nausea, nervousness, insomnia, loss of appetite, headache, mood changes, and urinary retention.

Figure 142-7. α -Sympathomimetic agents potentially have their greatest effect in the bladder neck region, where the highest concentration of α -adrenergic receptor sites exists. They can raise outlet resistance and improve continence in many individuals. BN, bladder neck; ES, external sphincter.

Surgical Treatment Options for Neuropathic Dysfunction of the Lower Urinary Tract

Botulinum Toxin

An alternative option for detrusor overactivity in neurogenic bladder is the intravesical injection of botulinum A toxin (BTA). BTA is a neurotoxin protein produced by the gram-positive bacterium *Clostridium botulinum*; it acts by inhibiting acetylcholine release, resulting in muscle paralysis. BTA has also been found to inhibit the release of other neurotransmitters including adenosine triphosphate and neuropeptides such as substance P, and to down-regulate the expression of purinergic and capsaicin receptors on afferent neurons within the bladder (Apostolidis et al, 2006; Chapple and Patel, 2006). The first use of BTA to treat neurogenic detrusor was in adults with spinal cord injury (Dykstra and Sidi, 1990). The first use in children with neuropathic bladder was documented in 2002 (Schulte-Baukloh et al, 2002). A systematic review of the use of BTA in children with neurogenic detrusor overactivity found that the most commonly injected dose is 10 IU/kg, with a maximum total dose of up to 300 IU. Most studies use 30 injection sites, sparing the trigone with rigid cystoscopy and using general anesthesia. Sixty-five percent to 87% of children in whom conservative medical management and CIC have failed have achieved dryness with a BTA injection (Riccabona et al, 2004). Improvements in urodynamic parameters include decreased maximum detrusor pressure (33% to 57%); increased maximum cystometric capacity (34% to 165%); and improved compliance (121% to 183%). The duration of response ranges from 6 to 10.5 months (Gamé et al, 2009). The most common minimal age for injection was 2 years, which corresponds to that approved by the FDA for the treatment of cerebral palsy (Gamé et al, 2009).

Overall, patient and caregiver satisfaction with this treatment exceeds 70% (Figuerola et al, 2014). Injection of BTA may allow approximately 25% of patients to discontinue antimuscarinic therapy after the first injection and an additional 10% after a second injection (Figuerola et al, 2014). Side effects from BTA are infrequently reported by patients (Kask et al, 2013). Side effects of intravesical BTA injection include urinary retention, UTI, hematuria, transient muscle weakness, dysuria, and pain (Duthie et al, 2011). It appears that repeated injections continue to be effective, with the interval between repeated injections increasing with each series of injections (Schulte-Baukloh et al, 2005; Altaweel et al, 2006). A reduction of dose in repeat injections (300 IU to 200 IU) was associated with recurrence of symptoms, which resolved with reinstitution of the original regimen (Figuerola et al, 2014). Injection of

intradetrusor BTA avoided bladder augmentation in close to 90% of children in whom first-line treatment with CIC and antimuscarinics had failed in one study (Figuerola et al, 2014). Serial injections of BTA show additional, significant improvement in urodynamic parameters, suggesting that tachyphylaxis, neutralizing antibody formation, or progressive fibrosis are not considerations with repeat BTA injections (Figuerola et al, 2014). This finding is supported by histopathologic examination of the detrusor. One study found no significant difference in edema, inflammation, or fibrosis when comparing children with neurogenic dysfunction before their first injection with those having had an intradetrusor injection of BTA previously. Repeated injections were associated with a significant decrease in the amount of fibrosis compared with those with no history of injection (Pascali et al, 2011).

Children who respond poorly to BTA intradetrusor injection have preexisting poor bladder compliance (Kask et al, 2013). Complete lack of a response to BTA injection has been linked to the presence of BTA antibodies (Schulte-Baukloh et al, 2008). One study compared injection of BTA in the detrusor to injection in both the detrusor and external urinary sphincter in 60 children with neurogenic dysfunction in whom CIC and antimuscarinic therapy had failed. More than 90% of the study population had DSD documented before injection of BTA. The researchers found that those with sphincter injection had a significant improvement in postvoid residual urine measurement and the presence of DSD on follow-up urodynamic studies; clinical parameters including constipation and incontinence trended toward improvement in the group with injections into the external urethral sphincter, although it was not a statistically significant difference (Safari et al, 2010). A larger study is required to confirm these preliminary findings.

Thus, intradetrusor injection of BTA is associated with improved continence and urodynamic parameters and may avoid reconstructive surgery in those in whom conservative management has failed. Serial injections are not associated with fibrosis or a decreased treatment effect.

For a thorough discussion of the surgical management of neurogenic bladder in children including augmentation, autoaugmentation, urinary diversion, bladder neck procedures, and the artificial urinary sphincter (AUS), please see the Expert Consult website.

Neuromodulation

Electrostimulation

Most studies of electrostimulation in pediatric neurogenic bladder involve a small sample size, often lack a control group, and have varied methods of electrostimulation and different outcome measures. Although some studies have shown improvement in clinical and urodynamic parameters, larger, prospective, randomized trials are required (Godec and Cass, 1978; Dexter et al, 1992, 1994; Balcom et al, 1997; Marshall and Boston, 1997; Han et al, 2004; Cirović et al, 2009; Kajbafzadeh et al, 2009, 2010; Choi et al, 2013a).

Sacral Neuromodulation

Sacral neuromodulation has been used extensively in children with non-neurogenic bladder dysfunction. Its use in children with neurogenic dysfunction has been limited. One prospective, randomized study of 42 children with SB comparing standard conservative management and sacral neuromodulation found that urodynamic variables did not differ between the two groups with the exception of better functional bladder capacity in the control group and lower leak point pressure in the neuromodulation group (Guys et al, 2004). Some of those in the implant group noted improved intestinal transit, resolution of UTI, and better sensation of a persistently full bladder (Guys et al, 2004). Seven percent of the neuromodulation group required revision surgery (Guys et al, 2004). Thus, sacral neuromodulation in this population appears to be safe with some limited benefits over standard therapy, but a larger study is required to determine its efficacy.

Surgical Management of Neuropathic Dysfunction of the Lower Urinary Tract

Augmentation

A persistent poorly compliant, small-capacity, or overactive detrusor may be treated with enterocystoplasty (Mitchell and Piser, 1987; Sidi et al, 1987). It is estimated that in the early 2000s, approximately 5.4% of children with SB underwent augmentation cystoplasty (Lendvay et al, 2006). Sigmoid, cecum, stomach, and small intestine have been used to enlarge the bladder. The ileocecal segment is avoided in children with myelodysplasia because removing it might aggravate the bowel dysfunction in these children (Bauer, personal communication, 2014). Detubularization of the bowel is needed to minimize the intrinsic contractions of the intestinal segment and prevent it from causing intractable incontinence once it has been added to the bladder (Goldwasser et al, 1987; Hinman, 1988).

Most studies evaluating outcomes for augmentation cystoplasty have patient populations with mixed causes (primarily neurogenic bladder but also other etiologies such as exstrophy-epispadias, posterior urethral valves, and so on), and augmentation cystoplasty is performed with and without concomitant procedures such as continent catheterizable channels, antireflux surgery, and bladder outlet procedures. Thus there are limited data that reflect the outcomes specifically in those with neurogenic bladder treated with augmentation cystoplasty in isolation. Continence is achieved in 90% or more (Shekarriz et al, 2000; Husmann and Cain, 2001; Quek and Ginsberg, 2003; Veenboer et al, 2013). Increased mean bladder capacity (Krishna et al, 1995; Quek and Ginsberg, 2003), improved compliance (Veenboer et al, 2013), and safe storage pressures (Krishna et al, 1995; Quek and Ginsberg, 2003) are achieved in most patients. Preexisting hydronephrosis resolves in up to 92% (Krishna et al, 1995).

Postoperative urodynamic studies may reveal regular phasic contractions (Robertson et al, 1991). It is unclear if these contractions arise from the bowel segment or the remaining bladder. These contractions are usually of low-amplitude activity (<40 cm H₂O), and are volume dependent, occurring only at volumes above 200 mL (Quek and Ginsberg, 2003). Zero to 29% of patients require antimuscarinics after augmentation (Mitchell et al, 1986; Luangkhot et al, 1991; Herschorn and Hewitt, 1998; Chartier-Kastler et al, 2000; Quek and Ginsberg, 2003).

Complications of Augmentation Cystoplasty. The complication rate of augmentation cystoplasty is approximately 30% (Metcalf et al, 2006b; Schlomer et al, 2013). Approximately half of those are considered to be major complications (Schlomer et al, 2013). Complications include small bowel obstruction (Schlomer et al, 2013), bleeding requiring transfusion (Schlomer et al, 2013), fistula (Schlomer et al, 2013), bladder perforation (Metcalf et al, 2006b), and recurrent UTIs or pyelonephritis (Flood et al, 1995; Bertschy et al, 2000; DeFoor et al, 2004). The need for further surgery is estimated to be 0.04 operations per patient per year. Further surgery may include surgical intervention for stones (11% to 63%) (Flood et al, 1995; DeFoor et al, 2004; Metcalf et al, 2006a), laparotomy for bowel obstruction (3.2% to 4%) (Flood et al, 1995; Metcalf et al, 2006a), closure of bladder perforation (4% to 13%) (Bauer et al, 1992; Flood et al, 1995; Krishna et al, 1995; Bertschy et al, 2000; Shekarriz et al, 2000; DeFoor et al, 2003; Metcalf et al, 2006b), and revision of or repeat augmentation (9.4% to 16%) (Flood et al, 1995; Metcalf et al, 2006a).

Risk factors for the development of stones in augmented bladders include excessive mucus production from enteric segments (Hensle et al, 2004), use of the ileal segment (DeFoor et al, 2004; Metcalf et al, 2006b), the presence of an abdominal stoma (Hensle et al, 2004), and an immobile patient with sensory impairment (Hensle et al, 2004). Stone formation is recurrent in up to 30% of patients (Flood et al, 1995; DeFoor et al, 2004). Regular irrigation with water or saline is recommended to decrease the rate of stone formation related to mucus (Hensle et al, 2004).

Bladder perforation is a life-threatening complication of bladder augmentation and requires prompt diagnosis and treatment. In some individuals it is a recurring problem (Metcalf et al, 2006b). Presenting symptoms include abdominal distention and pain, septic shock, and shoulder pain related to diaphragmatic irritation from extravasated urine (Bauer et al, 1992). Sepsis resulted in death in 25% of patients with bladder perforation in one series (Bauer et al, 1992). Those with a history of bladder outlet procedures seem to be at increased risk (Bauer et al, 1992; Metcalf et al, 2006b). It appears that those with a catheterizable abdominal stoma are at lower risk of perforation (Metcalf et al, 2006b), perhaps because of increased compliance with catheterization schedules (Horowitz et al, 1995). There is controversy about which bowel segment is at highest risk of rupture; some studies have identified the sigmoid colon as the most likely to perforate, although most of the sigmoid segments in this series were not detubularized (Metcalf et al, 2006b), whereas others have found that ileum is the most likely to rupture (Bauer et al, 1992). Because of the risk of sepsis and death, diagnosis and treatment should be prompt. Cystography (either fluoroscopic or with computed tomography [CT]) is diagnostic in most but not all cases (Bauer et al, 1992; Slaton and Kropp, 1994). It is postulated that overdistention and relative ischemia related to bowel detubularization are important in the pathophysiology of rupture (Bauer et al, 1992). The gold standard approach to management of this problem is exploratory laparotomy and closure of the perforation; however, conservative management with drainage of the urinary reservoir and percutaneous drainage of abdominal urinoma in patients without hemodynamic instability or worsening symptoms has been described (Slaton and Kropp, 1994; Leyland and Masters, 2003).

Long-term metabolic complications are also common with augmentation cystoplasty. Concerns have surfaced about gastric segments because they can cause hyponatremic hypochloremic metabolic alkalosis (Gosalbez et al, 1993) or the hematuria dysuria syndrome (Castellan et al, 2012). Except for children with progressive or end-stage renal failure, gastrocystoplasty is not recommended currently as a routine form of augmentation (Chadwick Plaire et al, 2000; Leonard et al, 2000). Augmentation cystoplasty with any segment of the gastrointestinal tract can lead to long-term consequences in acid-base balance, vitamin B₁₂ deficiency, fat absorption, renal function changes, aberrant bone metabolism, and growth retardation (Gilbert and Hensle, 2005).

It has been suggested that patients with SB are at increased risk for bladder cancer (Austin et al, 2007). Proposed risk factors for the development of malignancy in SB include chronic UTI, stone disease, repeated catheterization, and incorporation of enteric segments (Mehan et al, 2011). Early reports suggested that intestinal and gastric bladder augmentation were associated with an increased risk of bladder cancer. The largest study found that bladder cancer developed in 0.6% of patients undergoing augmentation (Metcalf et al, 2006a). Most studies note a 10-year minimum lag time between the augmentation and presentation of disease. Presenting symptoms are often atypical and may include vague abdominal pain, gross hematuria, urosepsis, renal failure, difficult catheterization, increasing frequency of UTI, new-onset hydronephrosis, and bladder wall thickening (Austin et al, 2007; Castellan et al, 2007; Vemulakonda et al, 2008; Veenboer and Kort, 2011). Age at presentation is younger than is typical for bladder cancer (Austin et al, 2007; Veenboer and Kort, 2011). One study found that almost 90% of patients had locally advanced disease or lymph node metastases at presentation (Austin et al, 2007). Urothelial cell carcinoma accounts for close to 60% of the tumors, followed by squamous cell carcinoma in 21%, adenocarcinoma in 16%, and signet cell tumor of the gastric augment in 5% (Austin et al, 2007). Some studies have disputed the association of enteric augmentation and an increased risk of malignancy. For example, there have also been reports of malignancy in those with autoaugmentation without incorporation of enteric segments (Mehan et al, 2011; Veenboer and Kort, 2011). In addition, several studies have found that enteric augmentation in this group does not result in a greater risk of

developing malignancy than in a comparable group of patients without augmentation (Austin et al, 2007; Higuchi et al, 2010). Most of these studies are compromised owing to relatively small study numbers and confounding factors, such as smoking history, exposure to known carcinogens, and family history, all of which are not addressed. Thus it is clear that patients with neurogenic bladder affected by bladder malignancy have a younger age at presentation, atypical symptoms, and advanced disease. Some, including the ICCS, have recommended annual surveillance cystoscopy and cytology starting 5 to 10 years after augmentation (Soergel et al, 2004; Castellán et al, 2007; Vemulakonda et al, 2008; Rawashdeh et al, 2012). However, there is insufficient evidence to determine the efficacy of screening for bladder cancer in this population (Kokorowski et al, 2011). In fact, four of six patients diagnosed with bladder cancer had no discernible mass noted on routine cystoscopic surveillance (Castellán et al, 2007; Vemulakonda et al, 2008). In addition, hypothetical models predict that screening for bladder cancer after augmentation cystoplasty is not cost-effective (Kokorowski et al, 2011).

Alternatives to standard augmentation cystoplasty have been sought to avoid the short- and long-term complications associated with this procedure. Although initial reports of autologous tissue-engineered bladder augmentation were promising (Atala et al, 2006), a recent phase II study showed that bladder capacity and compliance were not improved and the incidence of serious adverse events was unacceptable (Joseph et al, 2014).

Autoaugmentation

Because augmentation with enteric segments has a significant risk for short- and long-term complications, some have advocated for autoaugmentation or detrusorrectomy (with or without demucosalized enteric segments) to treat small and poorly compliant neurogenic bladders (Cartwright and Snow, 1989a; 1989b). Although some series have shown short-term improvement in bladder capacity, compliance, and maximum detrusor pressures (Hansen et al, 2013), when compared with enteric augmentation, those who have had autoaugmentation are more apt to be incontinent, use antimuscarinics, and have worse compliance (Marte et al, 2002; MacNeily et al, 2003; Veenboer et al, 2013). The incidence of de novo hydronephrosis (30%) (MacNeily et al, 2003) and VUR (Marte et al, 2002) in autoaugmentation is unacceptably high. The failure rate of autoaugmentation and need for subsequent augmentation cystoplasty ranges from 15% to 45% (Marte et al, 2002; MacNeily et al, 2003; Hansen et al, 2013; Veenboer et al, 2013). The lack of long-term improvement in urodynamic parameters and continence, combined with the high failure rate, make autoaugmentation an undesirable option.

Urinary Diversion

Urinary diversion, once considered a panacea for children with myelodysplasia, has turned out to be a Pandora's box of new clinical problems (Schwarz and Jeffs, 1975; Shapiro et al, 1975). Pyelonephritis and renal scarring, urinary tract calculi, ureterointestinal obstruction, strictures of the conduit, and stomal stenosis are often encountered in children who are monitored on a long-term basis. In recent times, urinary diversion is rarely performed unless accompanied by a continent catheterizable stoma.

Incontinent Urinary Diversion. Button vesicostomy using a gastrostomy button was first described in 1996 (de Badiola et al, 1996). It has the advantage of being readily reversible and can be used as a temporary measure. The incidence of minor complications such as transient leakage, wound infection, and overgranulation are expected in 40%, with 17% requiring removal or replacement of the device because of infection, device failure, and significant leakage (Bradshaw et al, 2014).

Vesicostomy drainage (Duckett, 1974; Mandell et al, 1981) is rarely required today but is reserved for those infants (1) who have such severe reflux that CIC and antimuscarinic medication fail to improve upper urinary tract drainage, (2) whose parents cannot

adapt to the catheterization program, or (3) who are not good candidates for augmentation cystoplasty (Morrisroe et al, 2005). It has been shown to improve renal function, hydronephrosis, and VUR in almost all patients undergoing the procedure (Queipo Zaragozá et al, 2003). Complications include bladder stomal prolapse, stomal stenosis, peristomal irritation, and vesical lithiasis (Queipo Zaragozá et al, 2003).

Ileovesicostomy is suggested to be advantageous over vesicostomy because an external appliance can be applied to the stoma that eliminates the need for diapers (Ching et al, 2014). Although short-term results look promising (Ching et al, 2014), long-term follow-up reveals that over half of children require reoperation or additional procedures (Tan et al, 2008; Hellenthal et al, 2009).

Urethral Dilation. External urethral dilation (up to 36 Fr in infants or up to number 18 Hegar dilators in older children) under general anesthesia has been described to address elevated leak point pressures in select children with neurogenic bladder dysfunction who have not responded to CIC and antimuscarinic therapy (Bloom et al, 1990). The mean number of dilations needed per patient is 1.6 (Park et al, 2001). The dilation in males can be achieved via perineal urethrostomy (Bloom et al, 1990; Miller et al, 2003). Durable (mean follow-up of 8 years) improvement has been demonstrated in mean leak point pressure, capacity, and initial and terminal compliance (Bloom et al, 1990; Park et al, 2001). Those with an elevated leak point pressure and good initial compliance seem to have the most long-lasting results from the procedure. However, upper urinary tract deterioration was noted in 20% by about 9.5 years after the dilation (Park et al, 2001). Approximately 43% have improvement in VUR and 64% have improvement or resolution of hydronephrosis (Kiddoo et al, 2006). Thus, urethral dilation may benefit a select group of children with neurogenic bladder in whom initial conservative measures fail but long-term follow-up is compulsory.

Bladder Neck Procedures

Artificial Urinary Sphincter. In children with low bladder outlet resistance, the AUS provides increased outlet resistance while maintaining the ability to catheterize per urethra. In children, the sphincter may be placed at the bladder neck or bulbar urethra (in males). The procedure is often performed in conjunction but not simultaneously with other procedures, such as augmentation cystoplasty to address poor compliance and low bladder volumes. Continence rates range from 63% to 86% (Simeoni et al, 1996; Spiess et al, 2002; Herndon et al, 2003; Catti et al, 2008). The need for revision ranges from 16% to 61% (Simeoni et al, 1996; Spiess et al, 2002; Catti et al, 2008), with erosion of the cuff noted in 16% to 20% (Simeoni et al, 1996; Castera et al, 2001; Catti et al, 2008). Worsening of bladder function is noted in 4% to 30% (Simeoni et al, 1996; Castera et al, 2001; Catti et al, 2008). This is seen more commonly in those with a preexisting poorly compliant or overly contractile bladder. Long-term surveillance is required in all patients because they may develop bladder hypertonicity after outlet resistance is increased, which can lead to upper urinary tract changes eventually causing renal failure (Castera et al, 2001). Patients with an AUS are less likely to void spontaneously if the sphincter is implanted before puberty or in conjunction with an augmentation cystoplasty (Catti et al, 2008). Mean operational life of the AUS ranges from 4.6 to 12.7 years (Simeoni et al, 1996; Castera et al, 2001; Spiess et al, 2002). Better continence outcomes are noted in those without a history of a prior bladder neck procedure (Castera et al, 2001).

Bladder Neck Slings. It is difficult to compare published data concerning the effectiveness of bladder neck slings in the treatment of bladder outlet incompetence, because most published series include patients with varied preoperative bladder function and previous or concurrent procedures, such as augmentation cystoplasty, bladder neck reconstruction, and continent catheterizable channels. As well, there is no standardized definition of continence. In addition, varied materials are used to perform the sling including rectus fascia (Bauer et al, 1989; Walker et al, 1995), bladder wall (Alboust et al, 2007), and small intestinal submucosa (Colvert et al,

2002; Misseri et al, 2005a). Success rates for continence appear to be similar with the varied sling materials, although rectus fascia is used most commonly. Both U-shaped and 360-degree type slings are described (Bauer et al, 1989; Snodgrass et al, 2007). And again, similar continence rates are noted. In those with decreased bladder compliance or hypercontractility, bladder neck slings are usually done in conjunction with augmentation cystoplasty, yielding continence rates of 30% to 93%, with most studies noting success in excess of 70% (Barthold et al, 1999; Dik et al, 1999; Walker et al, 2000; Albouy et al, 2007; Churchill et al, 2010). Continence rates for females tend to be better than for males treated with a bladder neck sling (Barthold et al, 1999; Colvert et al, 2002). Most studies note that bladder neck slings do not lead to difficulty with catheterization (Albouy et al, 2007; Dean and Kunkle, 2009; Churchill et al, 2010). Some have advocated for the use of a bladder neck sling alone, without augmentation, in children with neurogenic sphincter deficiency, bladder underactivity, and a detrusor leak point pressure below 25 cm H₂O (Snodgrass et al, 2007). Continence, defined as two or fewer wet pads per day, is noted in 83% (Snodgrass et al, 2007). However, as noted in those with increased outlet resistance after placement of an AUS (Bauer et al, 1986), these patients are at risk for developing hypercontractility and decreased bladder compliance. Approximately one third of patients treated with a tight 360-degree bladder neck sling develop increased bladder pressures and/or overactive detrusor contractions (Snodgrass et al, 2007; Snodgrass and Barber, 2010). Most of these children responded to antimuscarinic treatment, although augmentation cystoplasty was required in 2 of 37 patients (5%) (Snodgrass and Barber, 2010; Snodgrass et al, 2010). Therefore if a bladder neck sling procedure is done in isolation, long-term surveillance is

required to monitor for changes in bladder function to prevent upper urinary tract deterioration. When compared with those who had a bladder neck sling without augmentation, those with augmentation had a longer interval between catheterizations, required less antimuscarinic medication, and scored higher on a health-related quality-of-life survey for achieving independence for self-directed care (Snodgrass et al, 2009). For children who do not achieve continence with a bladder neck sling, placement of an AUS is more likely to be effective than injection of periurethral bulking agents (Barthold et al, 1999).

Injection of Periurethral Bulking Agents

Over time, the type of material injected to increase outlet resistance at the bladder neck has changed; currently the most commonly used agent is dextranomer/hyaluronic acid (Alova et al, 2012; DaJusta et al, 2013). Success rates for achieving complete continence with retrograde, transurethral injection of the bladder neck are low, ranging from 7% to 50%, with deterioration in results over time (Guys et al, 2001; Godbole et al, 2003; Misseri et al, 2005b; Guys et al, 2006; Lottmann et al, 2006; De Vocht et al, 2010; Alova et al, 2012; DaJusta et al, 2013). Repeat injections do not appear to be beneficial (De Vocht et al, 2010; Alova et al, 2012). Success in those with antegrade injection of bulking agents and suprapubic catheter drainage postinjection is much better, ranging from 70% to 78% (Dean et al, 2007; Kaye et al, 2010; Alova et al, 2012). Thus, although the success rates are low, bladder neck injection of bulking agents does achieve dryness for some children with neurogenic sphincter deficiency. Antegrade injection has superior success rates compared with retrograde injection.

Artificial Somatic-Autonomic Reflex Pathway Procedure

The artificial somatic-autonomic reflex pathway is a promising new therapeutic approach to restore bladder function in children with SB. The procedure involves a limited laminectomy and a lumbar ventral root to S3 ventral root microanastomosis. The L5 dorsal root is left intact as the afferent branch of the somatic-autonomic reflex pathway after axonal regeneration (Xiao et al, 2005). In a series of 20 children with SB, 17 developed satisfactory bladder control and continence within 12 months of the procedure. Those children with DSD and overactivity demonstrated nearly normal storage and synergic voiding on follow-up urodynamic studies (Xiao et al, 2005). A recent study at an independent center confirmed early favorable results with improved continence, bowel function, and spontaneous voiding in 30% of the SB patients (median age 8 years) who underwent intradural lumbar to sacral motor root microanastomosis. Postoperative complications included prolonged wound drainage, ipsilateral footdrop, and temporary lower extremity muscle weakness (Peters et al, 2010). Others have found variable results and in some cases no improvement in bladder function (Nouhaud et al, 2011; Tuite et al, 2013). Thus this novel approach appears to have promising results when performed by experts. The long-term results and general application of the procedure have yet to be determined.

KEY POINTS: MEDICAL AND SURGICAL TREATMENT OPTIONS

- Antimuscarinic therapy and CIC are the mainstays of therapy.
- Bladder pressures should be maintained below 30 cm H₂O as much as possible to prevent urinary tract deterioration.
- Intravesical injection of botulinum toxin is well tolerated and avoids the need for more invasive treatment options in a high proportion of children, with minimal side effects.
- Enterocystoplasty is an effective option to prevent deterioration of upper tracts but comes with a high risk of complications.
- Patients undergoing isolated bladder neck procedures (AUS and bladder neck sling) may develop hypercontractility and poor compliance that lead to upper tract deterioration, mandating close follow-up.

MANAGEMENT OF VESICoureTERAL REFLUX IN NEUROPATHIC DYSFUNCTION OF THE LOWER URINARY TRACT

VUR occurs in 3% to 5% of neonates with myelodysplasia, usually in association with poor detrusor compliance, detrusor overactivity, and/or DSD (Flood et al, 1994). It is rare to find reflux in any neonate without these urodynamic findings (Bauer, 1984; Geraniotis et al, 1988; Edelstein et al, 1995). If left untreated, the incidence of reflux in these infants at risk increases with time until 30% to 40% are affected by 5 years of age (Bauer, 1984; Seki et al, 1999). In children with reflux grades I to III (International Classification) who void spontaneously or have a complete lesion with little or no bladder outlet resistance and who empty the bladder completely, management consists solely of prophylaxis with antibiotics to prevent recurrent infection. In children with high-grade reflux (grade IV or V), CIC is begun to ensure complete emptying. Children who cannot empty the bladder spontaneously, regardless of the grade of reflux, are treated with CIC to empty the bladder efficiently.

Children with poor detrusor compliance with or without hydro-ureteronephrosis are also started on antimuscarinic agents to lower intravesical pressure and ensure adequate upper urinary tract decompression (Flood et al, 1994). When reflux is managed in this manner there has been a dramatic response, with reflux resolving in 30% to 55% of individuals (Kass and Koff, 1981; Bauer, 1984;

Joseph et al, 1989; Flood et al, 1994; Agarwal et al, 1997; Hopps and Kropp, 2003). Although bacteriuria can occur in as many as 56% of children on CIC, it is not harmful except in the presence of high-grade reflux, because symptomatic urinary infection and renal scarring rarely occur with lesser grades of reflux (Kass and Koff, 1981; Cohen et al, 1990).

Credé voiding should be avoided in children with reflux, especially those with a reactive external urethral sphincter. In this circumstance, the Credé maneuver results in a reflex response in the external sphincter that increases urethral resistance and raises the pressure needed to expel urine from the bladder (Barbalias et al, 1983) (Fig. 142-8). This has the effect of aggravating the degree of reflux and accentuating its water hammer effect on the kidneys.

The indications for antireflux surgery in this group of children are not very different from those applicable to children with normal bladder function. They include recurrent symptomatic (febrile) urinary infection while the child is receiving adequate antibiotic therapy and appropriate catheterization techniques; persistent hydronephrosis despite effective emptying of the bladder and lowering of intravesical pressure; and severe reflux with an anatomic abnormality at the ureterovesical junction.

Jeffs and colleagues were the first to show that antireflux surgery can be very effective in children with neurogenic bladder dysfunction as long as it is combined with measures to ensure complete bladder emptying (Jeffs et al, 1976). Before this observation was made, the results of ureteral reimplantation were so dismal that most physicians treating these children advocated urinary diversion as a means of managing reflux (Smith, 1972; Cass, 1976). Since the advent of CIC, success rates for antireflux surgery have approached 95% (Kass and Koff, 1981; Woodard et al, 1981; Kaplan and Firlit, 1983). Bilateral surgery for unilateral disease need not be done, because contralateral reflux does not occur postoperatively (Bauer, 1984a).

In patients with low-grade reflux who are undergoing augmentation cystoplasty, most clinicians have found acceptable resolution

Figure 142-8. When the external sphincter is reactive (A), a Credé maneuver produces a reflex increase in electromyographic (EMG) activity of the sphincter and a concomitant rise in urethral resistance, resulting in high voiding pressure. A child whose sphincter is denervated and nonreactive (B) will not have a corresponding rise in EMG activity, urethral resistance, or voiding pressure. A Credé maneuver here will not be detrimental. (From Bauer SB. Early evaluation and management of children with spina bifida. In: King LR, editor. Urologic surgery in neonates and young infants. Philadelphia: Saunders; 1988. p. 252–64.)

rates of VUR without ureteral reimplantation (Morioka et al, 1998; López Pereira et al, 2001; Helmy and Hafez, 2013). However, for those with high-grade reflux (grades III and greater) treated with augmentation cystoplasty alone, persistence of VUR ranges from 20% to 47% (Morioka et al, 1998; Wang et al, 2011; Helmy and Hafez, 2013). Thus, children with high-grade reflux undergoing augmentation cystoplasty should have concurrent ureteral reimplantation (Morioka et al, 1998; Wang et al, 2011; Helmy and Hafez, 2013).

The endoscopic injection of various materials has altered the management of reflux in children with MMC (Schlussel, 2004). Success rates of 73% with one injection and 91% with two injections have been reported for the endoscopic management of VUR in those with neurogenic bladder dysfunction (Misra et al, 1996; Estornell Moragues et al, 2008). It has been suggested that success rates of endoscopic therapy in children with neurogenic bladder do not differ from those with a normal bladder (Routh et al, 2008). Higher success rates approaching 95% have been noted when endoscopic treatment of VUR is paired with intravesical injection of botulinum toxin (Neel et al, 2008; Neel, 2010).

However, the durability of this approach has been questioned, with one study showing that 40% of those with initial success with endoscopic management had VUR recur at a mean of 4.5 years after the initial treatment (Polackwich et al, 2012). Studies comparing the effectiveness of open surgical to endoscopic management in this population show a significantly greater success rate for traditional open procedures (84.3% to 95.5% vs. 61% to 72.5%) (Engel et al, 1997; Granata et al, 1999). Thus, the endoscopic approach is a reasonable alternative to ureteroneocystotomy; however, long-term outcomes raise concerns about the durability of this approach in those with neurogenic bladder dysfunction.

KEY POINTS: MANAGEMENT OF VESICoureTERAL REFLUX

- Low-grade reflux in those who are emptying well without outlet resistance can be managed with antibiotic prophylaxis alone.
- Patients with high-grade reflux or who are not emptying well also require CIC.
- Those with poor compliance with or without hydronephrosis should be started on antimuscarinics.
- The Credé maneuver is contraindicated in reflux.
- Indications for surgery for reflux are similar to those for children without neurogenic bladder. Success rates are similar if effective bladder emptying is addressed.

LIPOMENINGOCELE AND OTHER SPINAL DYSRAPHISMS

Presentation

There is a group of congenital defects that affect the formation of the spinal column but do not result in an open vertebral canal (James and Lassman, 1972) (Box 142-2). They occur once in 4000 live births, but with the ease of MRI screening of children with

suspected lesions, the detected incidence of these defects is increasing (Bruce and Schut, 1979). The incidence of lipomeningocele in families was calculated to be 0.043% (Sebold et al, 2005). These lesions can be very subtle and have no obvious outward signs, but in more than 90% of children there is a cutaneous abnormality overlying the lower spine (Anderson, 1975; Pierre-Kahn et al, 1997). This varies from a small dimple or skin tag to a tuft of hair, a dermal vascular malformation, a very noticeable subcutaneous lipoma, or an asymmetrically curving gluteal cleft (Fig. 142-9). In addition, on careful inspection of the legs, one may note a high arched foot or feet; hammer toes or claw toes; a discrepancy in muscle size, leg length, and decreased strength in one leg compared with the other, typically at the ankle; and/or a gait abnormality, especially in older children (Dubowitz et al, 1965; Weissert et al, 1989; Jindal and Mahapatra, 2000). Absent perineal sensation, back pain, and secondary incontinence after a period of dryness are common symptoms in older children and young adults (Linder et al, 1982; Yip et al, 1985; Weissert et al, 1989). LUT function is abnormal in 40% to 90% of affected older individuals, with the incidence of an abnormality increasing proportionately with age (Mandell et al, 1980; Koyanagi et al, 1997; Pierre-Kahn et al, 1997; Sarica et al, 2003). The child may experience difficulty with toilet training, urinary incontinence after an initial period of dryness once toilet trained (especially during the pubertal growth spurt), recurrent urinary infection, and/or fecal soiling. Occasionally, some patients without an obvious back lesion escape detection until they develop urinary (66%) or lower extremity (19%) symptoms or back pain (14%) after puberty, caused by delayed traction on the spinal cord (Satar et al, 1995).

When these children are evaluated in the neonatal period or early infancy, a majority have perfectly normal neurologic examination findings (Atala et al, 1992). Urodynamic testing, however, reveals abnormal LUT function in about one third of infants younger than 18 months (Keating et al, 1988) (Fig. 142-10). Such studies may provide the only evidence of a neurologic injury involving the lower spinal cord (Keating et al, 1988; Foster et al, 1990; Atala et al, 1992; Satar et al, 1995; Nogueira et al, 2004). When present, the most likely abnormality is an upper motor neuron lesion characterized by an overactive detrusor and/or hyperactive sacral spinal cord reflexes (Fone et al, 1997; Pierre-Kahn et al, 1997); mild forms of DSD are rarely noted. Lower motor neuron signs with denervation potentials in the sphincter or an acontractile detrusor occur in only 10% of young children.

In contrast, practically all individuals older than 3 years who have not been operated on or in whom an occult dysraphism has been belatedly diagnosed have either an upper or a lower motor neuron lesion or a combination thereof on urodynamic testing (92%) (see Fig. 142-10) or neurologic signs of lower extremity dysfunction (Yip et al, 1985; Kondo et al, 1986; Keating et al, 1988; Atala et al, 1992; Satar et al, 1995; Nogueira et al, 2004). When such children were observed expectantly from infancy after the diagnosis was made, 58% experienced deterioration of their disorder within 2 years (Andar et al, 1997; Cornette et al, 1998). There does not seem to be a preponderance of one type of lesion over another (i.e., upper vs. lower motor neuron), and often the child shows signs of both (Hellstrom et al, 1986; Kondo et al, 1986). In one study of children older than 3 years, 43% had denervation in the sphincter and 52% had an acontractile detrusor, with a total of 81% having an abnormality (Satar et al, 1995).

Pathogenesis

Various occult spinal dysraphic lesions produce different neurourologic findings. When they do cause an abnormality, lipomas of the cauda equina invariably cause an upper motor neuron lesion (70%), alone or in combination with a lower motor neuron deficit (30%) (Satar et al, 1995). The split cord syndrome results in an isolated upper or lower motor neuron lesion in 25% each or a combined lesion in 50% (Proctor et al, 2000).

The reason for this difference in neurologic findings may be related to (1) compression of the cauda equina or sacral nerve

BOX 142-2 Types of Occult Spinal Dysraphisms

Lipomeningocele
Intradural lipoma
Diastematomyelia
Tight filum terminale
Dermoid cyst or sinus
Aberrant nerve roots
Anterior sacral meningocele
Cauda equina tumor

Figure 142-9. Cutaneous lesions occur in 90% of children with various occult dysraphic states. These lesions vary from a small lipomeningocele (A) to a hair patch (B), a dermal vascular malformation (C), a dimple (D), or an abnormal gluteal cleft (E).

roots by an expanding lipoma or lipomeningocele (Yamada et al, 1983), (2) tension on the spinal cord from tethering secondary to differential growth rates in the bony vertebrae and neural elements while the lower end of the cord is held in place by the lipoma or by a thickened filum terminale (Dubowitz et al, 1965), or (3) fixation of the split lumbosacral cord by an intravertebral bony spicule or fibrous band (Pang, 1992; Pang et al, 1992; Andar et al, 1997). The overt stretching that invariably occurs when there is a forcible flexion and/or extension of the spinal cord with normal movement leads to changes in oxidation and reduction of cytochrome oxidase, most notably in the lumbosacral spinal neurons when there is no intraspinal pathologic process (Yamada et al,

1983; Henderson et al, 2005). Under normal circumstances the conus medullaris ends just below the L2 vertebra at birth and recedes upward to T12 by adulthood (Barson, 1970). When the cord does not “rise” or is fixed in place owing to one of these lesions, ischemic injury may ensue (Yamada et al, 1981, 2004). Correcting the lesion in infancy has resulted not only in stabilization but also in improvement in the neurologic picture in many instances (Koyanagi et al, 1997; Cornette et al, 1998; Proctor et al, 2000) (Fig. 142-11). Sixty percent of infants with abnormal urodynamic findings preoperatively revert to normal postoperatively, with improvement noted in 30%; 10% become worse with time. In older children there is a less dramatic change after surgery, with only 27%

Figure 142-10. Most neonates with an occult spinal dysraphism have normal lower urinary tract function, whereas older children tend to have both upper motor neuron (UMN) and lower motor neuron (LMN) lesions.

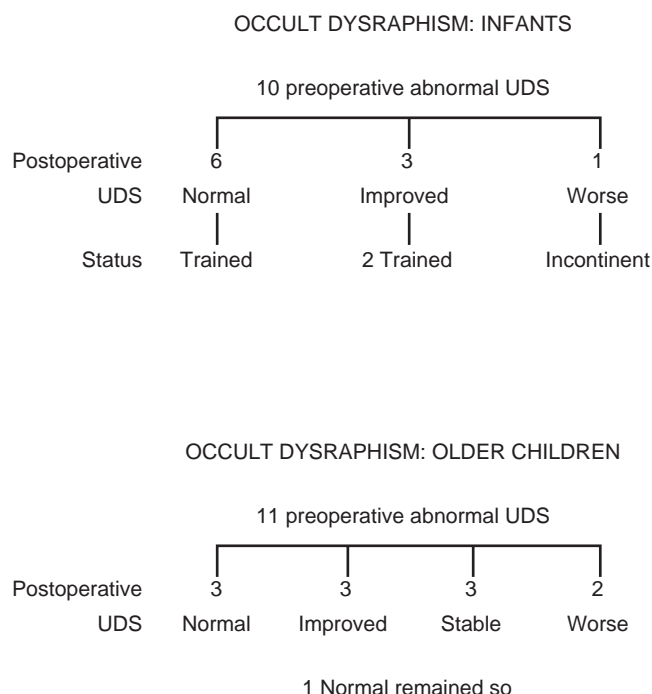

Figure 142-11. The potential for recoverable function is greatest in infants (6 of 10, 60%) and less so in older children (3 of 11, 27%). The risk of damage to neural tissue at the time of exploration in those with normal function is small (2 of 19, 11%). UDS, urodynamic study.

becoming normal, 27% improving, 27% stabilizing, but 19% actually becoming worse with time (see Fig. 142-11) (Keating et al, 1988; Satar et al, 1995). Older children with an overactive detrusor tend to improve, whereas those with acontractile bladders do not (Flanigan et al, 1989; Hellstrom et al, 1986; Kondo et al, 1986). Finally, 5% to 27% of children operated on in early childhood develop secondary tethering when observed for several years, suggesting that early surgery has both beneficial and sustaining effects in patients with this condition (Satar et al, 1995; Pierre-Kahn et al, 1997; Proctor et al, 2000).

As a result of these findings, it is apparent that urodynamic testing may be the only way to document that an occult spinal dysraphism is actually affecting lower spinal cord function (Keating et al, 1988; Khoury et al, 1990; Pierre-Kahn et al, 1997; Sarica et al, 2003). The serial use of electromyography (EMG) of the external urethral sphincter using a needle electrode to monitor individual motor unit action potentials provides a precise mechanism for measuring changes in innervation that may occur over time. Some investigators have shown that posterior tibial somatosensory evoked potentials are an even more sensitive indicator of tethering and should be an integral part of the urodynamic evaluation (Roy et al, 1986). The implication of these findings lies in the fact that early

detection and early intervention can either reverse or at least stabilize the progression of the lesion, which does not happen in older children (Yamada et al, 1983; Kaplan et al, 1988) and offers a degree of protection from subsequent tethering (Satar et al, 1995; Pierre-Kahn et al, 1997; Proctor et al, 2000), which seems to be a frequent occurrence when the lesion is not dealt with expeditiously in infancy (Chapman, 1982; Seeds and Jones, 1986) (see Fig. 142-11). Improvement of urodynamic parameters is most likely to occur in those undergoing neurosurgical repair for lipomeningocele in the first 12 months of life, compared with those aged 12 to 36 months. Those children undergoing surgery after 36 months of age were least likely to have improvement in their urodynamic findings (Rendeli et al, 2007). Thus, early intervention provides better outcomes for motor and bladder function.

Specific Recommendations

In addition to MRI studies (Tracy and Hanigan, 1990), urodynamic testing including EMG of the external urethral sphincter should be performed in every child who has a questionable cutaneous or bony abnormality of the lower spine, especially if there is a radiologic abnormality of the spinal cord (Packer et al, 1986; Campobasso et al, 1988; Hall et al, 1988; Meyrat et al, 2003). This test provides the most accurate measure of sacral spinal cord function at diagnosis and provides a basis for comparison with subsequent studies when the children are either operated on or carefully observed. In children younger than 3 months of age, the vertebral bones have not ossified; thus a window of opportunity exists for ultrasonography to be a useful screening tool in visualizing the spinal canal (Fig. 142-12) (Raghavendra et al, 1983; Scheible et al, 1983). At this age there is good correlation between the ultrasound imaging and MRI findings; however, if a spinal cord abnormality is identified, MRI provides a better definition of the spinal cord lesion. Consequently, ultrasonography should not be used as the definitive imaging modality (Hughes et al, 2003). Older children with an occult spinal cord lesion may have urologic symptoms in 20% of cases (Hsieh et al, 2006), and 50% to 60% may have abnormal urodynamic findings preoperatively (Guerra et al, 2006). Resolution of the abnormal urodynamic parameters is noted in 50% to 60% of patients after detethering (Guerra et al, 2006; Hsieh et al, 2006). Therefore, urodynamic study is recommended for all children with an occult spinal dysraphism before and after spinal cord detethering procedures. In addition to urodynamic studies, all children should have a renal and bladder ultrasound at presentation (Bauer et al, 2012).

In the past, most of these conditions were treated by excising the superficial skin lesion, without dissecting further into the spinal canal to remove or repair the entire abnormality. Currently, most neurosurgeons advocate laminectomy and removal of the intraspinal process as completely as possible without injuring the nerve roots or cord to release the tether and prevent further injury with subsequent growth (Linder et al, 1982; Kondo et al, 1986; Kaplan et al, 1988; Foster et al, 1990; Atala et al, 1992; Pierre-Kahn et al, 1997; Proctor et al, 2000). Long-term urologic follow-up is recommended, according to the guidelines put forth by the ICCS, summarized in Table 142-2 (Bauer et al, 2012).

SACRAL AGENESIS

Presentation

Sacral agenesis has been defined as the absence of part or all of two or more lower vertebral bodies. The presentation is bimodal, with more than three fourths of children being detected in early infancy and the remainder discovered between 4 and 5 years of age (Wilmschurst et al, 1999). With the increased use of prenatal ultrasonography, it is being diagnosed with increased frequency before birth. Sacral vertebral bony ossification begins at 15 weeks, so it is possible to detect the lesion after 18 weeks of gestation on an ultrasound examination and then to confirm it by fetal MRI (De Biasio et al, 2003). When not detected prenatally or at birth, the

Figure 142-12. A, During the first few months of life, ultrasonography can clearly demonstrate intravertebral anatomy because the posterior arches have not completely ossified. Note that the spinal cord along with its central canal is displaced anteriorly (*white arrows*) beginning at L3 because of an intradural lipoma. B, The magnetic resonance image is juxtaposed to confirm the ultrasound findings. The longitudinal white intraspinal mass (*black arrows*) is the lipoma; the longitudinal gray mass is the spinal cord.

KEY POINTS: LIPOMENINGOCELE AND OTHER SPINAL DYSRAPHISMS

- Children with an occult NTD often are presented after age 3 or 4 years with incontinence or constipation. They may have new urologic symptoms after a growth spurt, related to tethering of the spinal cord. Most have a cutaneous abnormality overlying the spine.
- Radiologic examination of the spine, MRI, and renal ultrasound are indicated in the initial evaluation. A spinal ultrasound may be used as a screening investigation before MRI in those younger than 3 months.
- Urodynamic studies should be done before and after spinal cord detethering.
- Intervention with spinal cord detethering early in life is associated with better outcomes than when done later.

diagnosis is often delayed until failed attempts at toilet training bring the child to the attention of a physician. Presenting urinary symptoms in those aged 4 years and older include urinary incontinence or constant dribbling in 85% and recurrent UTI in 74%. VUR may be seen in up to 65% (Emami-Naeini et al, 2012). Sensation, including that in the perianal dermatomes, is usually intact, and lower extremity function is normal (Koff and Deridder, 1977; Capitanucci et al, 1997). Because these children have normal sensation and little or no orthopedic deformity in the lower extremities (although high arched feet or claw toes or hammer toes may be present), the underlying lesion is often overlooked. In fact, 20% escape detection until the age of 3 or 4 years (Guzman et al, 1983). The only clue, besides a high index of suspicion, is flattened buttocks with a low, short gluteal cleft (Bauer, 1990) (Fig. 142-13). Palpation of the coccyx is helpful in detecting the absent vertebrae

Figure 142-13. Characteristically, in sacral agenesis the gluteal crease is short and is seen only inferiorly (*below arrow*) because of the flattened buttocks.

(White and Klauber, 1976). The diagnosis is most easily confirmed with a lateral film of the lower spine, because this area is often obscured by the overlying gas pattern on an anteroposterior projection (White and Klauber, 1976; Guzman et al, 1983) (Fig. 142-14). MRI has been used to visualize the spinal cord in these patients; it reveals a sharp cutoff of the conus at T12 as a consistent finding (Pang, 1993; Diel et al, 2001) (Fig. 142-15).

Figure 142-14. The diagnosis of partial or complete sacral agenesis (arrows) is easily confirmed on an anteroposterior (A) or lateral (B) radiograph of the spine if bowel gas obscures the sacral area. (From Bauer SB. Early evaluation and management of children with spina bifida. In: King LR, editor. Urologic surgery in neonates and young infants. Philadelphia: Saunders; 1988. p. 283–310.)

Figure 142-15. Coronal (A) and sagittal (B) magnetic resonance images in a 10-year-old boy with sacral agenesis beginning at L5. Note the squared lower limit of the cord adjacent to T11 (A, upper arrows; B, white arrow) and the two sacroiliac joints (A, lower arrows), which are in the midline because of absence of the sacrum. C, An anteroposterior radiograph from an excretory urogram shows no vertebral bodies below L4 (arrow).

Figure 142-16. Bladder contractility is unrelated to the number of absent vertebrae. (From Bauer SB. Early evaluation and management of children with spina bifida. In: King LR, editor. Urologic surgery in neonates and young infants. Philadelphia: Saunders; 1988. p. 283–310.)

On urodynamic evaluation an almost equal number of individuals manifest either an upper or a lower motor neuron lesion (35% vs. 40%, respectively); 20% to 25% have no sign of denervation (Guzman et al, 1983; Boemers et al, 1994a). The number of affected vertebrae does not seem to correlate with the type of motor neuron lesion present (Boemers et al, 1994a) (Fig. 142-16). The injury appears to be stable and rarely shows signs of progressive denervation as the child grows. Sacral sensation is relatively spared, even in the presence of extensive sacral motor deficits (Boemers et al, 1994a). UTI may be detected in 75% of children over time, with VUR diagnosed in 37%. Reflux is most likely to occur in those with an upper (75%) (irrespective of whether they have synergy or dyssynergy) versus a lower (40%) motor neuron lesion (Wilmschurst et al, 1999).

Pathogenesis

The cause of this condition is still uncertain, but teratogenic factors may play a role, because insulin-dependent diabetic mothers have a 1% chance of giving birth to a child with this disorder. Conversely, 16% or more of children with sacral agenesis have a mother who is insulin dependent with diabetes mellitus (Passarge and Lenz, 1966; Guzman et al, 1983; Wilmschurst et al, 1999). Often the mothers have only gestational insulin-dependent diabetes. The disease has been reproduced in chicks by exposing embryos to insulin (Landauer, 1945; White and Klauber, 1976). Maternal insulin-antibody complexes have been noted to cross the placenta, and their concentration in the fetal circulation is directly correlated with macrosomia (Menon et al, 1990). It is possible that a similar cause-and-effect phenomenon occurs in sacral agenesis. There is evidence that a deletion of the seventh chromosome (7q36) leading to the absence of a transcription factor may be responsible for this anomaly (Papapetrou et al, 1999). In addition, maternal drug exposure (i.e., minoxidil) has been reported to cause sacral agenesis (Rojansky et al, 2002).

In familial cases of sacral agenesis associated with the Currarino syndrome (presacral mass, sacral agenesis, and anorectal malformation), deletions in chromosome 7 (7q) resulting in *HLXB9* genetic mutations have been found (Ross et al, 1998). A mutation in *HLXB9*, a homeodomain gene of a 403-amino acid protein that appears to be responsible for neural plate infolding, has been identified in 20 of 21 patients with familial cases and in 2 of 7 sporadic cases of Currarino syndrome (Hagan et al, 2000; Köchling et al, 2001). Heterozygote carriers within these families have also been identified (Lynch et al, 2000). Thus, sacral agenesis may represent one point on a spectrum of abnormalities that encompasses sacral meningoceles and anorectal malformations (Bernbeck et al, 2004).

Specific Recommendations

Because most children who are diagnosed with this condition have a neurologic deficit, urodynamic testing is mandatory at the time of diagnosis. Renal ultrasonography and nuclear or conventional cystography should be included as part of the evaluation process, especially if the child has a history of UTI or findings of an upper motor neuron lesion on urodynamic testing. Additional imaging studies may be required based on the child's history and findings from baseline studies.

Management depends on the specific type of neuromuscular dysfunction seen on urodynamic testing. Antimuscarinic agents should be given to children with upper motor neuron findings of detrusor overactivity, whereas CIC and α -sympathomimetic medications may have to be given to individuals with lower motor neuron deficits who cannot empty their bladders or stay dry between catheterizations. When antimuscarinic medication is ineffective in controlling the overactive detrusor, augmentation cystoplasty may be required to attain an adequate organ for urinary storage. Failure of α -sympathomimetic agents may necessitate either endoscopic injection of bulking agents or even AUS implantation to increase bladder outlet resistance. The bowels manifest a similar picture of dysfunction and need as much characterization and treatment as the LUT. Anorectal manometry has identified abnormalities in the internal anal sphincter and in voluntary anal sphincter squeeze pressure, leading to weakness of the muscle and concomitant fecal incontinence (Morera and Nurko, 2003). It is important to identify these individuals as early as possible so that they can become continent and out of diapers at an appropriate age, thus avoiding the social stigma of fecal or urinary incontinence.

KEY POINTS: SACRAL AGENESIS

- The index of suspicion for sacral agenesis should be high in children with incontinence or UTIs with a short gluteal cleft and/or flattened buttocks.
- The children of diabetic mothers or mothers with gestational diabetes are at increased risk.
- Initial investigation includes urodynamics, renal ultrasound, and nuclear cystogram.
- Long-term follow-up is required.

CONDITIONS OF THE PELVIS

Anorectal Malformation

Presentation

Anorectal malformations encompass a wide spectrum of diseases involving the distal anus and rectum as well as the urinary and genital tracts. The abnormalities may be minor with an excellent prognosis or very complex with poor functional outcomes (Levitt and Peña, 2007). This malformation occurs in approximately 1 in every 5000 live births (Levitt and Peña, 2007). The International (Krackenbeck) Classification of anorectal malformations separates entities into major clinical groups according to the location of fistula and rare or regional variants (Box 142-3) (Holschneider et al, 2005). Urinary tract abnormalities have been noted in 26% to 52% of affected children, with renal agenesis (primarily left-sided) and VUR as the most common associated findings (Parrott, 1985). The highest incidence of an abnormality is in those children with a high (70%) (supralelevator insertion of fistula) versus a low (infralelevator) (35%) lesion (Shaul and Harrison, 1997; Emir and Söylet, 1998), with boys more prone than girls to having an anomaly (50% vs. 29%) (Metts et al, 1997).

Spinal bony abnormalities range in incidence from 30% to 44%, but patients with a high lesion are more likely to be affected (48% to 54%) than those with a low lesion (15% to 27%) (Carson et al, 1984; Tsakayannis and Shamberger, 1995; Long et al, 1996). Spinal

cord abnormalities including a tethered cord, thickened or fatty filum terminale, and lipoma have been noted in 18% to 50% of patients, with the incidence varying proportionately in relation to the height of the rectal lesion (Shaul and Harrison, 1997). Neurogenic bladder dysfunction is a frequent finding (Kakizaki et al, 1994), usually manifesting as incontinence, but its occurrence is rare when no spinal cord malformation exists (Hulthén de Medina et al, 2004) (Fig. 142-17). It often manifests when the child is older and the parents have difficulty with toilet training.

Anorectal malformations may be nonsyndromic or may occur in conjunction with many different syndromes (Levitt and Peña, 2007). Important examples of syndromic anorectal malformations include VACTERL syndrome (vertebral anomalies, anal atresia, cardiac malformations, tracheoesophageal fistula, renal anomalies, and limb abnormalities), MURCS (müllerian duct aplasia, renal aplasia, and cervicothoracic somite dysplasia), OEIS (omphalocele, exstrophy, imperforate anus, and spinal defects), and Currarino syndrome (anorectal malformation, sacrococcygeal defect, presacral mass) (Currarino et al, 1981; Levitt and Peña, 2007).

The most common finding on urodynamic testing is an upper motor neuron lesion with an overactive detrusor and/or DSD (Boemers et al, 1994b; Taskinen et al, 2002; Borg et al, 2009), but a lower motor neuron lesion with an acontractile detrusor and a denervated sphincter may be seen as well (see Fig. 142-17) (Greenfield and Fera, 1991; Taskinen et al, 2002). Leak point pressures in excess of 40 cm H₂O, decreased compliance, and low bladder capacity have been noted (De Filippo et al, 1999; Stathopoulos et al, 2012). Normal urodynamic studies do not exclude a vertebral anomaly or myelodysplasia (Stathopoulos et al, 2012).

Children with Currarino syndrome are noted to have a tethered spinal cord in more than 80% of cases (Lee et al, 2012a). Postoperative voiding complaints including urgency, frequency, incontinence, and UTI are noted in approximately 80% (Lee et al, 2012a). Upper urinary tract changes such as hydronephrosis and VUR are not uncommon (Lee et al, 2012a). Surgical untethering of the spinal cord results have variable outcomes for urodynamic abnormalities, with some showing improvement, worsening, or no change (Lee et al, 2012a). Urodynamic abnormalities include small capacity, poor compliance, detrusor overactivity, DSD, and high voiding pressure (Lee et al, 2012a).

Pathogenesis

The cause of anorectal malformations remains unclear. It is most likely multifactorial, with some genetic component (Levitt and Peña, 2007). Although evidence for risk factors in the development

of anorectal malformations is limited, paternal smoking, maternal obesity, and maternal pregestational and gestational diabetes are associated with increased risk (Zwink et al, 2011). The cause of neurogenic bladder in these children is most commonly associated with a spinal cord abnormality. The posterior sagittal anorectoplasty (PSARP) approach espoused by Peña (1986) minimizes the chances of injuring the pelvic nerves that innervate the pelvic floor muscles and does not appear to result in iatrogenic neurogenic bladder dysfunction (De Filippo et al, 1999; Borg et al, 2009). Eighteen percent to 35% of those with anorectal malformations are noted to have neurogenic bladder (Mosiello et al, 2003a; Borg et al, 2009; Stathopoulos et al, 2012). Almost all have abnormal urodynamic findings before PSARP (Borg et al, 2009) and are usually (Borg et al, 2009) but not always (De Filippo et al, 1999; Stathopoulos et al, 2012) associated with a spinal cord abnormality.

Specific Recommendations

Initial evaluation in the neonatal period should include a careful inspection of the perineum looking for a fistulous site from the bowel, an examination of the upper and lower extremities, and an assessment of the spine and spinal cord (Carson et al, 1984; Mosiello et al, 2003a). Because of the high rate of associated genitourinary abnormalities, renal-bladder ultrasound is indicated in all children with an anorectal malformation (Levitt and Peña, 2007). Abnormalities on the renal ultrasound such as hydronephrosis and renal asymmetry should be further investigated with a VCUG.

Not all patients with a spinal cord abnormality have a bony defect, so intraspinal imaging in all children with anorectal malformations is recommended to ensure the presence of a normal spinal cord (Rivosecchi et al, 1995; Mosiello et al, 2003a; Miyasaka et al, 2009). Ultrasonography of the spine is recommended if the child is younger than 3 months because the vertebral bodies have not ossified, or a spinal MRI to rule out any abnormal intraspinal process is recommended in those older than 3 months (see Figs. 142-12 and 142-17) (Barnes et al, 1986; Tunell et al, 1987; Emir and Söylet, 1998; Mosiello et al, 2003a).

Urodynamic studies are reserved for those children with a bony abnormality of the spine, a spinal cord defect, or the telltale signs of dysfunction on VCUG or renal ultrasonography (Taskinen et al, 2002; Mosiello et al, 2003a). These studies should be conducted early in infancy before the child has had any definitive surgery for the imperforate anus and again after a pull-through operation has been performed on the rectum to determine, respectively, the true incidence of neurogenic bladder dysfunction and any changes that might have occurred as a result of the surgery (Borg et al, 2009). The presence of an abnormality on urodynamic testing in early infancy may warrant either intervention at that time to correct a spinal cord defect or watchful waiting to determine whether the lesion is progressive. Urodynamic studies are repeated subsequently or performed for the first time if secondary urinary or fecal incontinence ensues (Taskinen et al, 2002). Long-term follow-up reveals that ESRD is rare, but it may occur in just under 2% of children with anorectal malformation (Giuliani et al, 2013). Thus, if neurogenic bladder dysfunction is noted, long-term follow-up with annual ultrasound and repeat urodynamic or other imaging studies as specified in Table 142-2 is recommended.

Pelvic Surgery**Presentation**

In children, exenterative pelvic surgery for sacrococcygeal teratoma (Ozkan et al, 2006), pelvic rhabdomyosarcoma or other pelvic neoplasms (Yeung et al, 1994), and Hirschsprung disease (Holschneider et al, 1982) are well known to have deleterious effects on bladder function.

Children who have surgical resection of sacrococcygeal teratomas are noted to develop neurogenic bladder dysfunction in 35% to 45% of cases (Gabra et al, 2006; Le et al, 2011). Common presenting symptoms include UTI and incomplete bladder emptying

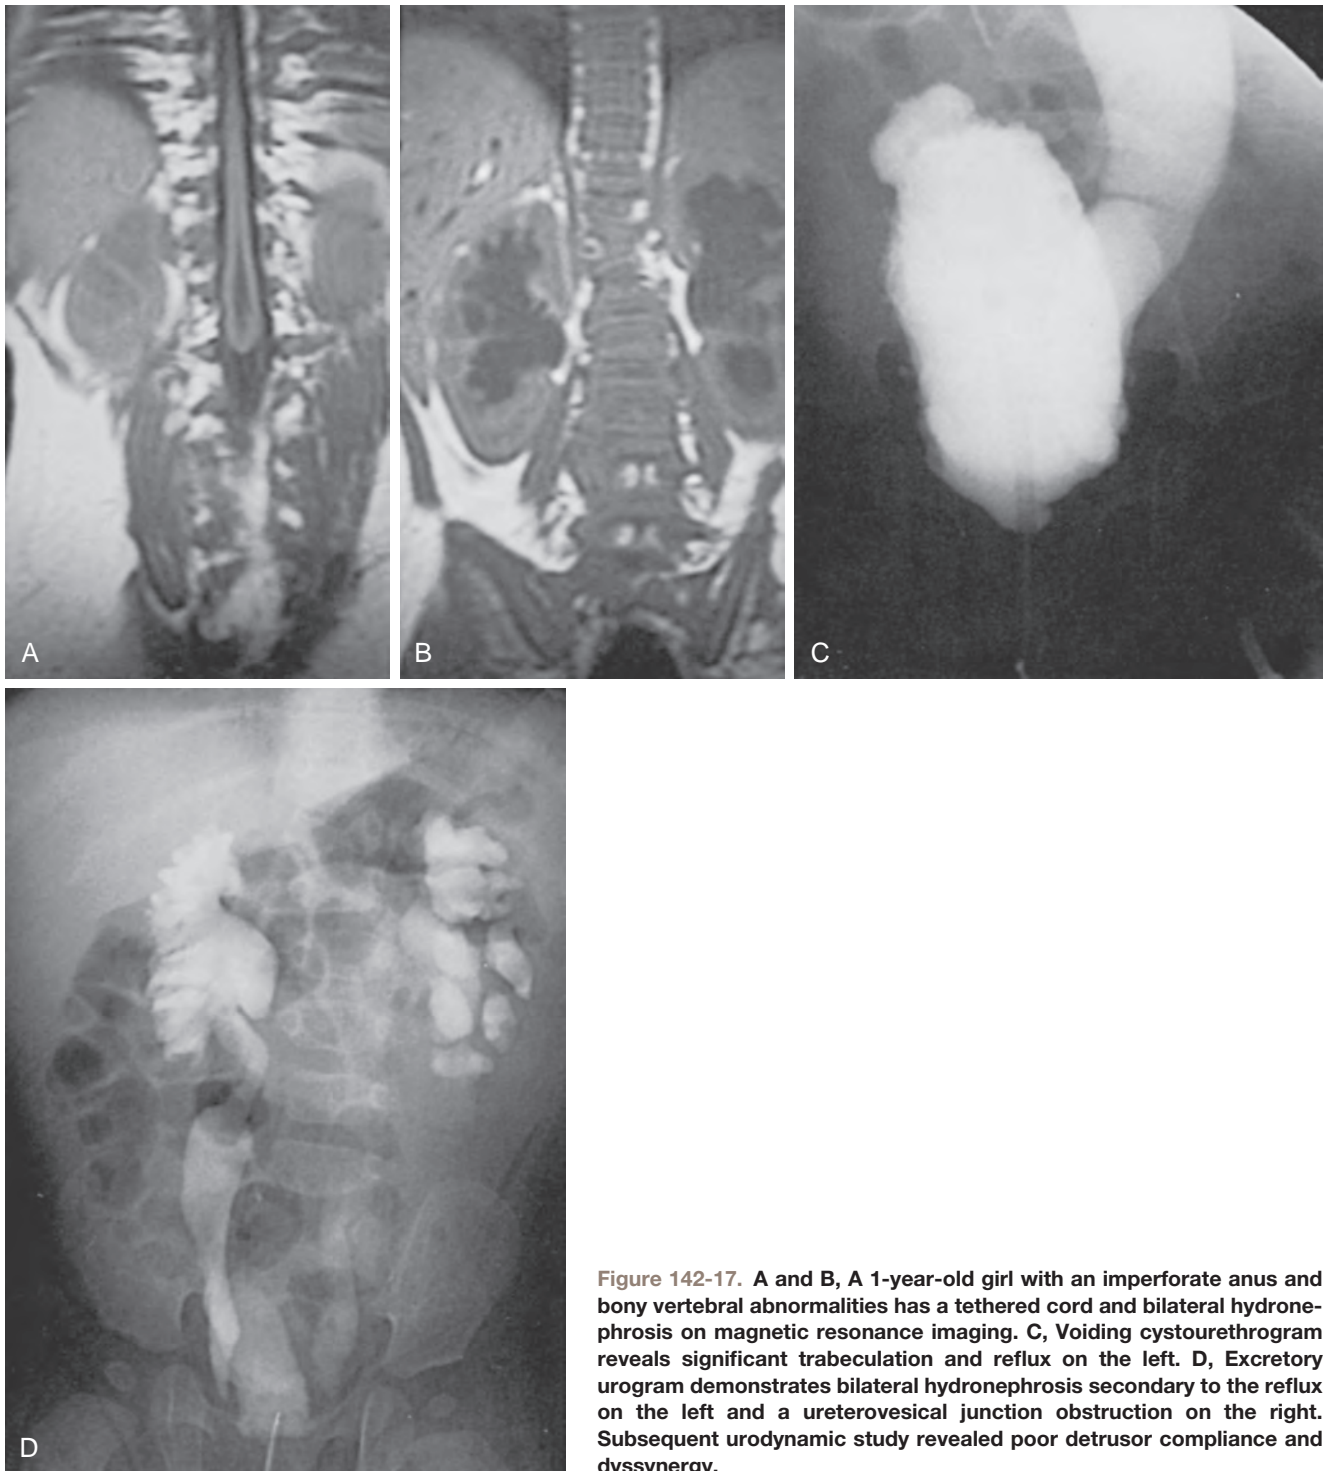

Figure 142-17. A and B, A 1-year-old girl with an imperforate anus and bony vertebral abnormalities has a tethered cord and bilateral hydronephrosis on magnetic resonance imaging. C, Voiding cystourethrogram reveals significant trabeculation and reflux on the left. D, Excretory urogram demonstrates bilateral hydronephrosis secondary to the reflux on the left and a ureterovesical junction obstruction on the right. Subsequent urodynamic study revealed poor detrusor compliance and dyssynergy.

(Ozkan et al, 2006). Urodynamic profiles reveal normal findings in 28% (Ozkan et al, 2006), detrusor overactivity in 57% to 81% (Boemers et al, 1994a; Ozkan et al, 2006), detrusor underactivity in 14% to 27% (Boemers et al, 1994a; Ozkan et al, 2006), poor compliance (Le et al, 2011), and DSD in 18% to 38% (Boemers et al, 1994a; Ozkan et al, 2006). Upper urinary tract deterioration may include renal scarring or decreased GFR (25%) (Le et al, 2011), VUR (25% to 50%) (Ozkan et al, 2006; Le et al, 2011), and hydronephrosis (30% to 43%) (Ozkan et al, 2006; Le et al, 2011). A tethered spinal cord can contribute to the neurogenic bladder abnormality in a small proportion of patients with sacrococcygeal teratoma (Boemers et al, 1994a; Mosiello et al, 2003b).

Children with genitourinary rhabdomyosarcomas in the past were uniformly treated with cystectomy. Currently, bladder preser-

vation is attempted when feasible (Raney et al, 2006). Children treated for pelvic neoplasms are noted to have normal bladder function postoperatively in 27% to 40% of cases (Mosiello et al, 2003b; Arndt et al, 2004; Hishiki et al, 2013). Those whose LUT dysfunction is symptomatic have nocturnal enuresis (26%) (Raney et al, 2006), daytime incontinence (14% to 27%) (Raney et al, 2006), urinary urgency (Soler et al, 2005), suprapubic pain with bladder filling (Soler et al, 2005), and UTIs (55%) (Raney et al, 2006). Urodynamic studies reveal markedly reduced functional bladder capacity (Yeung et al, 1994; Soler et al, 2005), detrusor overactivity (Mosiello et al, 2003b; Soler et al, 2005), detrusor underactivity (Mosiello et al, 2003b), and DSD (Mosiello et al, 2003b). Those children treated with bladder preservation strategies for pelvic rhabdomyosarcoma, especially those who receive radiation therapy,

are at high risk for LUT symptoms and upper urinary tract deterioration (Yeung et al, 1994; Soler et al, 2005; Raney et al, 2006). Abnormal renal function has been noted in one third, and hydronephrosis in 15% (Raney et al, 2006). Urinary tract reconstruction or diversion was ultimately required in close to 20% in one large series (Raney et al, 2006).

Up to 45% of children with Hirschsprung disease will have unstable detrusor contractions, which often resolve after the abnormal bowel is resected (Boemers et al, 2001). Transient urinary retention is noted in up to 7% of children undergoing surgery for Hirschsprung disease (Ateş et al, 2007). From 0% to 6% of children are noted to have urinary incontinence postoperatively with long-term follow-up (Holschneider et al, 1982; Boemers et al, 2001). Approximately one third of these children will have normal urodynamic findings postoperatively (Boemers et al, 2001). Two thirds have an increased maximum cystometric capacity (Boemers et al, 2001), and a high postvoid residual urine volume is noted in 55% to 78% (Boemers et al, 2001; Ateş et al, 2007). Poor compliance is rarely noted (Boemers et al, 2001). Different surgical approaches are noted to have varying effects on bladder function (Ateş et al, 2007).

Pathogenesis

Surgery of the pelvic viscera can result in damage to the pelvic splanchnic nerves, the hypogastric nerves, or the pelvic nerve plexus, resulting in autonomic denervation. Parasympathetic denervation (injury to the pelvic splanchnic nerves) may result in an acontractile bladder. Sympathetic denervation (injury to the hypogastric nerves) may cause a loss of bladder compliance and incompetence of the bladder neck. Mixed patterns of bladder dysfunction may be seen with injury to the pelvic plexus (Woodside and Crawford, 1980; Blaivas and Barbalias, 1983; Chang and Fan, 1983; Yalla and Andriole, 1984; Leveckis et al, 1995).

Specific Recommendations

The risk for upper urinary tract deterioration in those undergoing resection of pelvic sacrococcygeal teratomas is high; therefore preoperative and postoperative urodynamic studies are recommended for all (Ozkan et al, 2006; Le et al, 2011). Long-term urologic follow-up is required with annual ultrasound and clinical review in those who demonstrate urodynamic abnormalities or symptoms. Those who are asymptomatic and/or demonstrate normal postoperative investigations do not require long-term further evaluation unless symptoms arise.

As the risk of upper tract deterioration in those undergoing surgery for pelvic rhabdomyosarcomas is relatively high, it is recommended that all survivors, particularly those who had radiation therapy, be carefully monitored for upper urinary tract and LUT dysfunction (Yeung et al, 1994). It is recommended that screening be carried out with a frequency volume chart (Yeung et al, 1994), with urodynamic and ultrasound investigation limited to those with dysfunction. Long-term urologic follow-up is required with annual ultrasound and clinical review in those who demonstrate urodynamic abnormalities or symptoms. Those who are asymptomatic and/or demonstrate normal postoperative investigations do not require long-term further evaluation unless symptoms arise.

Because children undergoing surgery for Hirschsprung disease are usually symptomatic if bladder function is altered, routine postoperative urodynamic testing is not recommended for everyone. However, all patients should be screened clinically preoperatively and postoperatively for abnormal LUT function and undergo ultrasonographic examination of the urinary tract (Boemers et al, 2001). Those who are symptomatic preoperatively should undergo urodynamic studies before surgery. Those who are symptomatic after surgery should have urodynamic studies completed 6 months after surgery to allow resolution of temporary neuropathia (Boemers et al, 2001). Long-term urologic follow-up is required with annual ultrasound and clinical review in those who demonstrate urody-

namic abnormalities or symptoms. Those who are asymptomatic and/or demonstrate normal postoperative investigations do not require long-term further evaluation unless symptoms arise.

CENTRAL NERVOUS SYSTEM INSULTS

Presentation

Cerebral palsy is the most common physical disability in childhood. A recent study in the United States found that approximately 3.3 of 1000 8-year-old children have a variable degree of cerebral palsy. Its prevalence varies by region. It is more common in black and white children than in those who are Hispanic and is 1.2 times more common in boys than girls (Kirby et al, 2011). Cerebral palsy is a disorder of the development of movement and posture causing limitations in activities and is the result of nonprogressive disturbances of the fetal or infant brain. Sensation, perception, cognition, communication, and behavior may also be affected (Richards and Malouin, 2013). The Gross Motor Function Classification System—Expanded and Revised (2007; GMFCS-E & R; <http://motorgrowth.canchild.ca/en/GMFCS/resources/GMFCS-ER.pdf>) is based on self-initiated movement, with emphasis on sitting, transferring, and mobility. This is a 5-level scale that ranges from 1 (walks without limitations) to 5 (transported in a manual wheelchair). Specific descriptions with relevant age band categories exist for each level.

Affected children will often achieve urinary continence, although later than their age-adjusted normal peers (Roijen et al, 2001). In general, daytime continence is achieved first, followed by nighttime continence within the next year. Overall, 14% (Silva et al, 2009) to 34% of children (Richardson and Palmer, 2009) are continent of urine. The median age for achieving continence in those with high intellectual capacity and diplegia or hemiplegia is 3.6 to 4.1 years. For those with low intellectual capacity and tetraplegia, this milestone is achieved much later (10.1 to 13.2 years) (Roijen et al, 2001). Most studies do not correlate mobility (or GMFCS level) with the achievement of continence (Ersoz et al, 2009; Silva et al, 2009; Murphy et al, 2012). One study of 97 children evaluated with a standardized dysfunction voiding symptom survey found that 1 of 4 who were able to walk had LUT dysfunction compared with 3 of 4 who were unable to do so ($P < .001$) (Silva et al, 2009). LUT symptoms were more prevalent as the children aged (Silva et al, 2009; Murphy et al, 2012).

The incidence of urinary symptoms in children with cerebral palsy varies among studies, ranging from 16 (Murphy et al, 2012) to 94% (Gündoğdu et al, 2013). Females are more likely than males to have LUT symptoms (Ersoz et al, 2009; Silva et al, 2009). The most common symptom is incontinence, occurring in 23% to 94%; most have noted a prevalence of 35% to 45% (Roijen et al, 2001; Richardson and Palmer, 2009; Murphy et al, 2012; Gündoğdu et al, 2013). Urgency and frequency have also been reported (Murphy et al, 2012). Monosymptomatic enuresis is seen in 3% (Richardson and Palmer, 2009) to 13% (Silva et al, 2009). UTI is also variable, occurring in 5% to 57% (Ersoz et al, 2009; Silva et al, 2009, 2010; Gündoğdu et al, 2013). On evaluation, constipation is detected in 33% to 66% (Silva et al, 2009, 2010; Gündoğdu et al, 2013). Upper urinary tract deterioration, defined primarily as hydronephrosis, is uncommon, occurring in less than 5%, with a range of 0.5% to 12% (Silva et al, 2009, 2010; Murphy et al, 2012; Gündoğdu et al, 2013). Other parameters of deterioration include asymmetric renal size, VUR, and microlithiasis (Silva et al, 2009; Murphy et al, 2012; Gündoğdu et al, 2013). Factors raising the risk of upper urinary tract deterioration include increasing age, clinical symptoms of DSD (retention, interrupted voiding, hesitancy), and recurrent UTI (Gündoğdu et al, 2013).

Pathogenesis

The cause of urinary tract symptoms in children with cerebral palsy may be related to abnormal LUT function rather than to decreased mobility or ability to communicate.

Normal urodynamic studies are found in one third of children with cerebral palsy (Silva et al, 2009). Detrusor overactivity is noted in approximately 30% (Murphy et al, 2012; Gündoğdu et al, 2013) to 61% (Decter et al, 1987). Detrusor underactivity is documented in 6% (Murphy et al, 2012). Bladder capacity is less than expected in 42% to 93% (Ersoz et al, 2009; Silva et al, 2009; Gündoğdu et al, 2013). DSD is found in approximately 12% (Decter et al, 1987; Gündoğdu et al, 2013).

Thirteen percent may have an elevated postvoid residual urine volume (Silva et al, 2009). Uroflow patterns include a bell-shaped curve in 63%, staccato pattern in 17%, intermittent pattern in 13%; plateau-shaped pattern in 3%, and tower-shaped pattern in 3% (Ersoz et al, 2009).

Specific Recommendations

Although many affected children may have LUT symptoms, upper urinary tract deterioration is rare. Therefore most can be managed initially with minimal investigation and conservative management. In those with frequency, urgency, and/or incontinence, initial investigation should include a urinalysis and culture to rule out UTI, and a minimally invasive uroflow and postvoid residual urine measurement. Conservative measures such as timed voiding with or without antimuscarinic therapy may be instituted. If these measures fail, further investigation with urodynamic studies may be indicated. In addition, children with factors known to be associated with upper urinary tract deterioration—that is, recurrent UTIs or clinical symptoms of DSD (urinary retention, interrupted voiding, hesitancy)—should receive a more aggressive investigation including renal and bladder ultrasound and urodynamic studies. VCUG is indicated in the presence of UTI or DSD.

CONDITIONS OF THE BRAIN (TUMORS, INFARCTS, ENCEPHALOPATHIES)

Presentation

Children with neurogenic bladder resulting from CNS tumors most commonly have urinary incontinence and urinary retention (Soler and Borzyskowski, 1998; Nguyen et al, 2010). Other presenting symptoms include UTI, straining or difficulty voiding, hydronephrosis, or urinary urgency (Soler and Borzyskowski, 1998; Nguyen et al, 2010). In some children, development of bladder symptoms heralds progression or recurrence of the disease (Soler and Borzyskowski, 1998).

Pathogenesis

Urodynamic studies of children with neurogenic bladder resulting from CNS tumors demonstrate poor compliance, inability to void, high voiding pressures, detrusor overactivity, and postvoid residual urine; on EMG, sphincter action potentials were both absent and present (Soler and Borzyskowski, 1998; Nguyen et al, 2010). There was no correlation between tumor location and any specific urodynamic parameter. Nor was there a difference in urodynamic findings in patients with intracranial versus extracranial tumors or in those with suprasacral versus sacral involvement (Nguyen et al, 2010).

There is little literature related to neurogenic dysfunction that arises from other brain conditions such as encephalopathies and infarcts in children. One study noted that the voided volume and rate of consciousness with voiding were significantly lower in newborns with hypoxic ischemic encephalopathy (HIE) than in those without HIE (Wen et al, 2012). Those with HIE had significantly higher postvoid residual urine volumes and voiding frequencies (Wen et al, 2012).

Specific Recommendations

Various types of storage and voiding dysfunction may occur independent of tumor location; routine urologic investigation including

Figure 142-18. Increasing frequency of spinal injury with age. (From Anderson JM, Schutt AH. Spinal injury in children: a review of 156 cases seen from 1958 through 1980. *Mayo Clin Proc* 1980;55:499–504.)

renal ultrasound and urodynamic studies in all children with CNS tumors is recommended (Soler and Borzyskowski, 1998; Nguyen et al, 2010). Children with encephalopathy may be at risk of bladder dysfunction and should be screened with clinical history. Those who are symptomatic should undergo investigation with renal ultrasound and urodynamic studies.

CONDITIONS OF THE SPINAL CORD

Traumatic Injuries

Presentation

Despite increased exposure to and the potential for traumatic spinal cord injuries, such injuries are rarely encountered in children. The incidence in Sweden is 2.6 cases per million children per year (Augutis and Levi, 2003). The incidence tends to increase geometrically with age (Anderson and Schutt, 1980) (Fig. 142-18). When an injury does occur, it is more likely to happen in a boy than a girl, and it is usually the result of a motor vehicle or bicycle accident (24% to 52%), a fall from a high place, a gunshot wound, or a diving or sports incident (Cass et al, 1984; Hadley et al, 1988; Decter and Bauer, 1993; Brown et al, 2001; Augutis and Levi, 2003; Cirak et al, 2004). The type of causative injury varies with age, with infants more prone to an injury from a motor vehicle accident (71%), toddlers and children more likely to be injured secondary to a fall (48% and 34%, respectively), and adolescents more likely to have a sports-related injury (29%) (Cirak et al, 2004). An injury may also occur iatrogenically after surgery to correct scoliosis, kyphosis, or other intraspinal processes or congenital aortic anomalies or after ligation of a patent ductus arteriosus (Cass et al, 1984; Batista et al, 1995). Neonates are particularly prone to a hyperextension injury during a high forceps delivery (Adams et al, 1988; Lanska et al, 1990). Among younger children, girls are affected as often as boys (Ruge et al, 1988).

Pathogenesis

Spinal cord injuries in children are intrinsically different from those in adults because of a variety of factors, including the mechanism of injury and the difference in configuration of the brainstem and spinal cord in children compared with adults. In addition, the horizontal versus vertical orientation of the facet joints in vertebral bodies that predisposes to anteroposterior subluxation in children, the delayed supportive effect of the paraspinous musculature and ligaments, and the relative heaviness of the

head, which causes a fulcrum of maximal flexion of the upper cervical region in infants and young children all contribute to a high degree of hypermobility that places the child's spinal cord at risk for ischemic necrosis (Decter and Bauer, 1993).

Specific Recommendations

The LUT dysfunction that ensues is not likely to be an isolated event but is usually associated with loss of sensation and paralysis of the lower limbs. Radiologic investigation of the spine may not reveal any bony abnormality, although momentary subluxation of osseous structures resulting from the elasticity of the vertebral ligaments can result in a neurologic injury (Pollack et al, 1988). This condition has been seen only in children (usually younger than 8 years) and has been designated *spinal cord injury without radiologic abnormality* (SCIWORA) (Pang and Wilberger, 1982; Pang and Pollack, 1989). Overall, SCIWORA can account for up to 38% of spinal cord injuries in children (Brown et al, 2001). Myelography and CT show swelling of the cord below the level of the lesion (Adams et al, 1988; Lanska et al, 1990). Often, what appears to be a permanent lesion initially turns out to be a transient phenomenon with time. Although sensation and motor function in the lower extremities may be restored relatively quickly, the dysfunction involving the bladder and rectum may persist considerably longer.

During the acute phase of the injury the bladder is often acontractile and the urethral sphincter nonreactive, although normal-appearing bioelectric potentials can be recorded on sphincter EMG (spinal shock). Over a variable period of time, detrusor contractility and sphincter reactivity return as spinal cord edema subsides. With this return of function, an overactive detrusor and bladder-sphincter dyssynergy develop if the lateral reticulospinal cord pathways to and from the brainstem have been disrupted. When the lesion affects the cauda equina, there is probably little to no return of bladder or urethral sphincter function. Sacral sensation and peripheral reflexes are not good indicators of ultimate LUT function (Shenot et al, 1998). Over time, the predominant urodynamic pattern in patients with a thoracic-level lesion is an overactive detrusor with DSD, high voiding pressures, eventual hydronephrosis, and VUR. Often children exhibit a highly compliant bladder for a portion of bladder filling but then have C-fiber-mediated, small, ineffective rhythmic contractions of the detrusor with simultaneous waxing and waning of external urethral sphincter activity. Some urinary leakage may occur with these contractions, but in general the bladder does not empty with them. Patients with an upper thoracic or cervical lesion are likely to exhibit autonomic dysreflexia with a spontaneous discharge of α_1 -stimulants during bladder filling and with contractions of the detrusor. Monitoring of blood pressure and availability of α -antagonists are mandatory during VCUG or urodynamic studies (Perkash, 1997; Vaidyanathan et al, 1998).

If urinary retention occurs immediately after the injury, an indwelling Foley catheter is passed into the bladder and left in place for as short a time as possible, until the patient's condition is stable and aseptic intermittent catheterization can be started safely on a regular basis (Guttmann and Frankel, 1966; Barkin et al, 1983). There is no difference in the incidence of urinary infection or in the development of stones in patients using sterile versus clean catheterization techniques to empty the bladder (Prieto-Fingerhut et al, 1997; Van Hala et al, 1997). Rates of infection range as high as 60% to 80% (Biering-Sørensen et al, 1999), and stone formation occurs in 1.5% to 3% within the first 5 years after the trauma (Donnellan and Bolton, 1999; McKinley et al, 1999). When the child starts to void again, the timing of catheterization can be regulated so that it is used as a means of measuring the residual urine after a spontaneous void. Residual urine volumes of 25 mL or less are considered safe enough to allow reducing the frequency or even stopping the catheterization program (Barkin et al, 1983). After 4 to 6 weeks, if there is no improvement in LUT function, urodynamic studies are conducted to determine whether the condition is the result of spinal shock or an actual nerve root or spinal cord injury. An acontractile detrusor is not uncommon under these

circumstances (Iwatsubo et al, 1985). On the other hand, EMG of the sphincter often reveals normal motor units without fibrillation potentials but absent sacral reflexes and a nonrelaxing sphincter with bladder filling, a sign that transient spinal shock has occurred (Iwatsubo et al, 1985). The outcome of this situation is guarded but good, because most cases resolve completely as edema of the cord in response to the injury subsides, leaving no permanent damage (Iwatsubo et al, 1985; Fanciullacci et al, 1988).

If and when bladder function returns and emptying is incomplete, it has been shown in the cat (Xiao et al, 1999) that peripheral L7 dermatome stimulation initiates a micturition reflex without DSD. In a preliminary study of 15 adults with spinal cord injury, detrusor overactivity, and DSD, the creation of an artificial somatic/CNS/autonomic reflex pathway resulted in satisfactory bladder control in 67% of patients. Follow-up urodynamic study revealed a change to almost normal storage and synergic voiding without DSD (Xiao et al, 2003). A more recent study showed satisfactory bladder control in 75% of patients with complete suprasacral spinal cord injury within 6 to 12 months. However, the mean and median time after the injury was 9 months, so the time from injury may have been a factor in this study (Lin et al, 2009). Incomplete emptying may be enhanced by the judicious use of α -sympatholytic agents (Al-Ali et al, 1999). The goal is balanced voiding at pressures lower than 40 cm H₂O, which reduces the 30% risk for urinary tract deterioration seen in poorly managed patients (Giannantoni et al, 1998; Kim et al, 1998). If this cannot be achieved, then CIC is continued. Antimuscarinics, either orally or intravesically (Vaidyanathan et al, 1998; Wein, 1998), or capsaicin (an inhibitor of C-fiber stimulation) (Wiart et al, 1998) have been added and are effective in reducing an overactive detrusor, but at the cost of significant side effects. Alternative treatments that have been effective to ensure complete emptying at low pressure include external urethral sphincterotomy (Kim et al, 1998), urethral stent placement (Chancellor et al, 1999), or injection of BTA into the external sphincter (Schurch et al, 1997; Kuo, 2003). In some cases, a continent catheterizable abdominal urinary stoma may be created to facilitate self-catheterization in patients with low cervical or upper thoracic lesions who cannot easily catheterize themselves (Sylora et al, 1997).

Most permanent traumatic injuries involve either the upper thoracic or the cervical spinal cord, but some affect the cauda equina region. The sacral cord injury most likely produces a lower motor neuron deficit of the striated urethral sphincter that usually leads to low-pressure bladder emptying with little risk of upper urinary tract deterioration. However, it probably necessitates medical and/or surgical therapy to achieve continence. On the other hand, upper spinal cord injuries produce an upper motor neuron-type lesion with an overactive detrusor and DSD. The potential danger from this outflow obstruction is obvious (Donnelly et al, 1972). Substantial residual urine volumes, high-pressure reflux, urinary infections, and their sequelae are the leading causes of long-term morbidity and mortality in patients with spinal cord injury (Giannantoni et al, 1998). Even patients who voluntarily urinate and are continent or who involuntarily but spontaneously void to completion are not immune to urinary tract changes (Decter and Bauer, 1993). Urodynamic studies are imperative to identify which patients are at risk (Barkin et al, 1983). These studies should be performed within 2 to 3 months after the injury, again 6 to 9 months later, and possibly at 2 years after the trauma to determine the stability of LUT function and the need for continued CIC and whether adjuvant drug or surgical therapy should be added (or continued) to achieve good long-term success. When these measures are employed judiciously, effective management can be achieved (Pannek et al, 1997). Renal ultrasonography early in the course and VCUG if signs of bladder outlet obstruction are present on urodynamic testing or if recurrent urinary infection ensues are also recommended. Radionuclide cystography is indicated if the patient has repeated UTI or develops hydronephrosis (Phillips et al, 1997). Because stone formation can be insidious, periodic imaging of the kidneys and bladder is necessary. Early identification and proper management may prevent the signs and effects of bladder outlet

obstruction before they become apparent on radiographic examination of the urinary tract (Pearman, 1976; Ogawa et al, 1988).

Transverse Myelitis

Presentation

Transverse myelitis is a clinical syndrome caused by an immune-mediated inflammatory process that affects the spinal cord (DaJusta et al, 2008). Approximately 1400 new cases are diagnosed in the United States annually, and 28% of affected individuals are children (Krishnan et al, 2004). The incidence peaks between 10 and 19 years of age and again in the third decade of life (Krishnan et al, 2004). Males and females have an equal incidence (DaJusta et al, 2008). The diagnosis of transverse myelitis is made by accepted criteria, including sensory, motor, or autonomic dysfunction attributable to the spinal cord, bilateral neurologic signs and/or symptoms, a clearly defined sensory level, and inflammation in the spinal cord as demonstrated by cerebrospinal fluid pleocytosis or an increased T2 signal on MRI (Fig. 142-19) (Krishnan et al, 2004).

Transverse myelitis usually manifests with sudden lower back pain or lower extremity muscle weakness that rapidly progresses to paralysis and often to urinary retention (Knebusch et al, 1998). Bladder dysfunction may occur simultaneously with the motor dysfunction or more commonly follows it (DaJusta et al, 2008). Bowel dysfunction is also likely to occur at presentation (DaJusta et al, 2008). In the acute stage of transverse myelitis there may be a varying period of spinal shock that may persist for up to 6 weeks (Guttmann, 1970) and that gradually progresses to spasticity. The segment of the spinal cord affected by the disease determines the motor deficit (DaJusta et al, 2008). During the acute phase of the disease, treatment options include steroids, plasma exchange, and intravenous immunoglobulin G (IgG) (DaJusta et al, 2008). Recovery from the disease usually commences within 2 weeks to 3 months after the onset of symptoms. The most significant recovery occurs within the first 6 months (DaJusta et al, 2008), but sometimes improvement continues up to 2 years after the event (Krishnan et al, 2004).

Pathogenesis

It is well documented that the most common urinary symptom in children with transverse myelitis is **urinary retention**; in fact,

Figure 142-19. Sagittal T2-weighted magnetic resonance image of the spine of an 8-year-old boy with lower extremity weakness and urinary retention. Increased signal intensity of the spinal cord is noted from T3 to T8 (arrows).

more than 95% of affected children have urinary retention during the acute phase of the disease (Gatti et al, 2001; Kalita et al, 2002; DaJusta et al, 2008). The most common urodynamic finding in the acute phase is areflexia or detrusor underactivity, found in close to 70% (Kalita et al, 2002). Detrusor overactivity is noted in the acute phase in approximately 13%; 30% have decreased compliance, and 20% may have DSD (Kalita et al, 2002). After resolution of spinal shock, the urodynamic patterns identifiable are detrusor overactivity (59% to 90%), decreased compliance (47%), DSD (17% to 80%), and detrusor leak point pressure greater than 40 cm H₂O (12% to 33%). Detrusor underactivity is noted rarely after resolution of the acute phase of the disease (Ganesan and Borzyskowski, 2001; Kalita et al, 2002; Tanaka et al, 2006).

Approximately one third of children will be able to void spontaneously after the acute phase (Tanaka et al, 2006; DaJusta et al, 2008). Some children (57% to 73%) will require CIC to empty their bladder (Tanaka et al, 2006; DaJusta et al, 2008). Antimuscarinic medications are needed to manage symptoms of detrusor overactivity in 14% to 64% (Ganesan and Borzyskowski, 2001; Tanaka et al, 2006; DaJusta et al, 2008). For children whose incontinence is not resolved with CIC and antimuscarinics owing to small capacity, poor compliance, or unremitting overactivity, injection of botulinum toxin and bladder augmentation have been helpful (Tanaka et al, 2006). Up to 77% may have persistent bowel dysfunction; consequently, most require active bowel management (Tanaka et al, 2006).

Although some reports have not correlated recovery of LUT function with recovery of motor function (Ganesan and Borzyskowski, 2001; Tanaka et al, 2006), other larger studies have demonstrated an association (Dunne et al, 1986; Kalita et al, 2002; DaJusta et al, 2008). One study found that children with full motor recovery were likely to also have full recovery of LUT function—that is, normal voiding with continence and no requirement for antimuscarinic medication. It was also noted that partial recovery of motor function was associated with partial recovery of LUT function, meaning that children could void spontaneously but required antimuscarinics for incontinence. Children with no motor recovery or those who were wheelchair dependent were likely to require CIC and possibly antimuscarinics (DaJusta et al, 2008).

Profound urologic complications have been noted infrequently in children with transverse myelitis including UTI (DaJusta et al, 2008), VUR (Tanaka et al, 2006), hydronephrosis (Tanaka et al, 2006), chronic renal insufficiency (Tanaka et al, 2006), bladder calculi (Kalita et al, 2002), and bladder diverticula (Kalita et al, 2002). One study documented an association between late initiation of CIC and an increased risk of decreased bladder compliance and upper urinary tract deterioration (Tanaka et al, 2006). In this series, upper urinary tract deterioration, where hydronephrosis or VUR was noted, occurred in 5% of children (Tanaka et al, 2006). In this series, neither neurologic examination nor urinary symptoms were able to predict the risk of upper urinary tract deterioration. In addition, ambulatory status did not correlate with urodynamic findings (Tanaka et al, 2006).

Specific Recommendations

Urodynamic studies and a baseline renal and bladder ultrasound once the acute phase of the neurologic injury has stabilized are suggested to identify those patients who may have DSD. Children with bladder underactivity and/or DSD will benefit from the early introduction of CIC and antimuscarinic therapy, respectively (Tanaka et al, 2006). Urodynamic studies should be performed again after resolution of the acute phase (at approximately 6 months) to guide therapy for incontinence and preservation of the upper urinary tract. Voiding or radionuclide cystography is indicated in the presence of DSD or UTIs. Because these children are at risk for upper urinary tract deterioration, annual follow-up evaluation including renal ultrasonography is recommended as outlined in Table 142-2. Urodynamic studies are advisable if there is a change in LUT symptoms or in sonographic images.

Daytime Urinary Incontinence and Bladder Dysfunction

Enuresis

CLINICAL SIGNIFICANCE

Functional disorders of the lower urinary tract (LUT) encompass abnormalities in the filling and/or emptying phases of the bladder and include a broad spectrum of clinical entities that vary in their cause and prognosis. These are functional disorders in that children do not have a readily identifiable neurologic or anatomic abnormality but rather the disorder is thought to originate from behavioral factors that affect toilet training and inhibit the development of normal urinary control. *LUT dysfunction (LUTD)*, *bladder and bowel dysfunction*, and the antiquated *dysfunctional elimination syndrome*, are terms that describe the common array of symptoms that include overactive bladder (OAB), voiding postponement, underactive bladder, dysfunctional voiding, primary bladder neck dysfunction, giggle incontinence, vaginal reflux, pollakiuria, and enuresis.

Evidence-based medicine lends support to the hypothesis that LUTD can predispose children to recurrent urinary tract infections (UTIs) and vesicoureteral reflux (VUR) with a potential for significant impact on subsequent LUT and renal function. Beyond these largely urologic sequelae, however, the impact of symptoms such as daytime incontinence are profound and can affect the behavioral, emotional, and social aspects of a child's daily life. Timely diagnosis and a coherent therapeutic approach are therefore paramount in the successful treatment of these physically and emotionally distressing disorders.

EPIDEMIOLOGY

LUTD is commonly encountered in daily practice, accounting for up to 40% of pediatric urology clinic visits annually (Feldman and Bauer, 2006). Cross-sectional studies confirm that functional LUT problems are prevalent, with 22% of school-age children reporting at least one LUT symptom. The most common urinary symptoms cited included holding maneuvers (19.1%) and urgency (13.7%) (Vaz et al, 2012).

United States

Daytime incontinence is estimated to affect up to 7 million children in the United States 6 years of age or older (Franco, 2012). OAB is the most commonly encountered LUT disorder in children and appears to have a peak incidence between 5 and 7 years of age, although its true prevalence is difficult to determine (Franco, 2007). To date, studies have focused primarily on daytime versus nighttime incontinence and have not attempted to differentiate the type of daytime incontinence. Chandra (1998) reported the responses to

583 questionnaires completed by families of children between 5 and 9 years of age and found that urinary urgency and pelvic tightening maneuvers to postpone voiding and prevent incontinence were the voiding issues most frequently reported. Urge incontinence was present in 7% of girls and 3% of boys (Chandra, 1998).

International

A study by Hellström and colleagues of 7-year-old Swedish children entering school revealed that 21% of girls and 18% of boys had moderate-to-severe urinary urgency. Daytime urinary incontinence occurred once weekly in 3.1% of girls and 2.1% of boys. A Japanese study of 6917 school-age children demonstrated an overall prevalence rate of 17.8% for OAB (Kajiwarara et al, 2006). Interestingly, this epidemiologic survey found a nearly equal prevalence of OAB between boys and girls of 19.1% and 16.6%, respectively. An Australian study addressed the frequency of voiding disorders in school-aged children (Sureshkumar et al, 2009). This study of 2856 students reported that 19.2% of children had experienced at least one episode of daytime incontinence in the previous 6 months, with 16.5% having experienced more than 1 wetting episode and only 0.7% experiencing wetting on a daily basis. Independent risk factors for daytime incontinence included nocturnal enuresis, female sex, history of UTI, and encopresis (Sureshkumar et al, 2009).

A large cross-sectional study of over 19,000 children between the ages of 5 and 13 was performed in the Republic of Korea and evaluated the prevalence of OAB by parental questionnaire (Chung et al, 2009). The overall prevalence of OAB was 16.6% and decreased with age from 23% to 12% by age 13 years (Chung et al, 2009). Compared with other children, those with OAB had a greater prevalence of nocturnal enuresis, constipation, fecal incontinence, UTI, delayed bladder control, and poor toilet facilities.

Gender and Age-Related Demographics

Robson (1997) and associates found that daytime incontinence varies with both age and gender. This group reported that the prevalence of daytime wetting at least once every 2 weeks was 10% in 5- to 6-year-old children, 5% from 6 to 12 years of age, and 4% from 12 to 18 years of age. In a population survey of 1192 individuals aged 1.5 to 27 years, daytime incontinence occurred in 13% of children aged 4 years, 7% of children aged 5 years, 10% of children aged 6 years, and 5% of children aged 7 years (Bloom et al, 1993). Studies on the prevalence of voiding disorders in school-age children indicate that daytime urinary incontinence is 2 to 5 times more common in girls (Sureshkumar et al, 2009). Hellström

and colleagues (1990) found that daytime incontinence was more common in girls (6.7%) than in boys (3.8%) and that most children with incontinence had other LUT symptoms (LUTS).

SELF-ESTEEM AND QUALITY-OF-LIFE ISSUES

Multiple epidemiologic and cross-sectional studies demonstrate that between 5% and 20% of children suffer with daytime incontinence (Hellström et al, 1990; Kajiwarra et al, 2004; Joinson et al, 2006; Sureshkumar et al, 2009). The reported incidence of incontinence ranges from 1.2% daily to 3.6% at least twice a week (Hellström et al, 1990). Remarkably, the majority of parents surveyed did not seek medical attention for their child's incontinence, and teachers recognized only 3% of the children in their classroom who actually suffered from daytime wetting (Sureshkumar et al, 2009). These statistics would make it appear that LUTD and its sequelae are of nominal consequence in the daily lives of young children. Various studies examining the impact of symptoms like urinary incontinence on self-esteem and quality of life in children would suggest otherwise.

Given the emerging recognition of patient perspectives in health care over the last decade, quality-of-life assessment is an important part of incontinence research. Measurement of quality of life in children with urinary incontinence gives a child-centric estimate of the impact that incontinence makes in daily life. In a survey study of 1185 children, both in the United States and Australia, school-age children were asked to grade the severity of 20 different stressful life events (Ollendick et al, 1989). Of the different situations examined, "Wetting pants in class" was rated as the third most stressful, which underscores the importance of urinary control in school-age children and their peers.

A recent article by Thibodeau and associates (2013) prospectively studied 40 children (10 males and 30 females), between 5 and 11 years of age with non-neurogenic daytime wetting. The Dysfunctional Voiding Symptom Score (DVSS), originally put forth by Farhat and colleagues (2000) was used to quantify the severity of LUTS and was completed by both parents and children. Parents and their children also completed the Pediatric Urinary Incontinence Quality of Life Score tool (PIN-Q), originally developed by Bower and coworkers (2006b), which measures the emotional impact that urinary incontinence has on a child. There was no statistically significant difference between parent and child scores for symptoms (DVSS) and quality of life (PIN-Q), indicating that parents were very aware of the child's symptoms and the impact they had. DVSS and PIN-Q responses were positively correlated (i.e., as DVSS scores increased the PIN-Q showed a corresponding rise).

COMORBIDITIES

Urinary Tract Infections

A clear and consistent relationship has been repeatedly demonstrated in multiple studies between LUTD and UTIs. What is unclear, however, is whether a causal relationship exists. This most likely is related to study design and interpretation. Bauer (2002) suggested that UTIs are not only an effect of dysfunctional voiding but also may precipitate the development of LUTD, specifically OAB.

Hellström and associates (1990) disseminated a questionnaire to analyze the micturition habits and UTI history to more than 3500 school-age children. Girls with daytime wetting, urgency, and emptying difficulties had a higher prevalence of a UTI history than those without symptoms. Hoebeke and colleagues (2001a) prospectively studied 1000 children during a 4-year study period with video-urodynamics to ascertain the cause and epidemiology of LUTD. The incidence of UTI was significantly higher in girls than in boys. In addition, boys with LUTD had no greater risk for UTI. In girls with underactive bladder there was a significantly higher incidence of UTI.

Chen and colleagues (2004) performed a multivariate analysis on 2759 children to elucidate the relationships among dysfunctional elimination, UTI, and VUR. Their data demonstrated a higher rate of LUTD in girls (43.7%) than in boys (23.8%), with 44% of children who had a history of UTIs also having concomitant LUTD. Interestingly, they observed no association of UTI or VUR individually, but rather found that LUTD was noted only when both UTI and VUR were present. This study challenges the contemporary paradigm espousing an independent association between UTI and LUTD.

In a recent retrospective review, Van Batavia and coworkers (2013) determined how many children who initially presented with LUTD had a history of UTIs. Of 623 children diagnosed with LUTD, one third had a history of UTIs, with the prevalence rate being significantly higher in girls than boys. When stratified by specific LUT conditions, girls with underactive bladder and dysfunctional voiding had the highest UTI rates. Not surprisingly, the association between UTIs and LUTD was most often noted for LUT conditions in which urinary stasis occurs.

Vesicoureteral Reflux

There is a known association between LUTD and VUR. Whether VUR is secondary to the LUT condition is controversial. Lapides and Diokono (1970) first described the association between dysfunctional voiding and VUR (Lapides and Diokono, 1970). Since that time a number of authors have expanded on the description and nature of the association. In the late 1970s, Koff and associates (1979) demonstrated that voiding against a closed sphincter can increase bladder pressure and may contribute to the development and persistence of VUR. The incomplete bladder emptying that occurs in children with LUTD can lead to urinary stasis with subsequent UTI causing inflammatory changes in the bladder wall that stimulate hypertrophy and overactivity. This is particularly true in older children who manifest with febrile UTIs after toilet-training has been completed. It has been theorized that detrusor hypertrophy can alter the closure mechanism at the ureterovesical junction, leading to reflux (Yeung et al, 1998).

One of the first studies to systematically address the relationship between LUTD and VUR was performed by Van Gool and associates (1992), who distributed a questionnaire to all children enrolled in the European arm of the International Reflux Study in Children. Extrapolating from the questionnaire results, the prevalence of dysfunctional voiding was approximately 18%. A strong association was observed between recurrent UTI and LUTD, and in those children with spontaneous resolution of their reflux, the prevalence of dysfunctional voiding was much lower.

Koff and associates (1998) reported their experience on 143 children with primary VUR who either resolved spontaneously or were surgically treated. LUTD was present in 66 (43% of the cohort), with 54 (82%) of these children having a breakthrough UTI and undergoing reimplantation compared to only 18% without LUTD. Of 70 children who had a breakthrough UTI, LUTD was present in 54 children (77%); in 73 patients who did not have a breakthrough infection, dysfunction was present in only 12 (16%) children. Additionally, if VUR resolution did occur, the time for resolution increased by 1.6 years in those with dysfunction compared to those without LUTD. Finally, unsuccessful surgical outcomes involving persistent, recurrent, and contralateral reflux occurred only in children with elimination disorders.

The association between LUTD and treatment failure after surgical correction for reflux has been borne out in a number of clinical studies. Regardless of surgical treatment modality (i.e., endoscopic vs. open reimplantation) ongoing LUTD has been shown to be associated with a higher failure rate. Capozza and colleagues (2002) treated a total of 320 children between 3 and 11 years of age with subureteral injection for grades II to IV VUR. They found untreated LUTD to be highly associated with endoscopic treatment failure at 6-month follow-up.

Targeted treatment for LUTD has been demonstrated to improve spontaneous resolution rates for VUR (Willemsen and

Nijman, 2000; Fast et al, 2013). In a recent study by Fast and coworkers (2013) patients diagnosed and treated for LUTD who had concomitant VUR at or near the time of diagnosis underwent targeted treatment for their specific dysfunction along with antibiotic prophylaxis. VUR was monitored with serial voiding cystourethrogram or video-urodynamics. After a mean of 3.1 years of treatment, VUR resolved with targeted therapy in 26 of 58 ureters. All of these patients had a history of UTIs before starting targeted intervention. Interestingly, they found that resolution rates for VUR were similar regardless of VUR grade. Resolution or significant improvement of reflux was greater in patients with dysfunctional voiding (70%) compared to those with OAB (38%) or underactive bladder (40%).

Psychological Associations

Recently, there has been an emerging awareness of the strong association that exists between neuropsychiatric comorbidities and LUTD in children. In fact, functional causes of LUTD are believed by many to originate from behavioral issues that evolve from personal stressors and/or adverse events that occurred around the time of toilet-training (Feldman and Bauer, 2006). If the LUTD is not addressed, this behavioral or learned response often will perpetuate itself. Limiting free access to a restroom or, worse, discouraging voiding in response to urgency in a child who has not developed complete cortical inhibition of voiding may alter normal coordination between bladder and sphincter (McKenna and Herndon, 2000).

Between 20% and 40% of children with daytime urinary incontinence are affected by comorbid behavioral disorders (von Gontard et al, 1998b; Joinson et al, 2006). Additionally, a number of epidemiologic studies have reported clinically significant behavioral problems in up to one third of children with enuresis (Hirasing et al, 1997; Liu et al, 2000). This is 2 to 4 times higher than children without enuresis and is comparable with rates of psychosocial problems in other pediatric chronic illness groups. Other studies have investigated the psychological problems associated with specific syndromes responsible for daytime urinary incontinence. These investigators found a higher rate of behavior problems in children with voiding postponement compared to those with urge incontinence as their major complaint (Lettgen et al, 2002; von Gontard et al, 2011a). Moreover, some have suggested that voluntary holding with postponement of voiding is acquired and may be reflective of ongoing behavioral issues (von Gontard et al, 1999).

Recently, Oliver and associates (2013) explored the prevalence of psychosocial comorbidities and their relationship to children presenting with LUTD (Oliver et al, 2013). Data were prospectively collected on patients 6 to 17 years of age. Parents completed a 21-question LUTS score based on a validated questionnaire and a psychosocial questionnaire that screened for stressful life events and psychological diagnoses. Of the 358 patients examined, 32% had a recent life stressor and 23% had a comorbid psychiatric disorder. Younger age correlated with a higher LUTS score. Children with a recent life stressor, psychiatric disorder, or the two comorbidities had a significantly higher LUTS score than children without comorbidities. This study lends support to the recommendation for screening of psychosocial comorbidities during the evaluation of pediatric LUTD.

In perhaps one of the largest epidemiologic studies to look at the association between daytime urinary incontinence and neuropsychiatric issues in children, researchers found a significantly increased rate of psychological problems among children who wet themselves compared to those who were dry (Joinson et al, 2006). Of the over 8000 children between 7.5 and 9 years of age who were studied, those with daytime wetting had significantly increased rates of attention-deficit/hyperactivity disorder (ADHD) (24.8%), conduct disorders (11.8%), separation anxiety (11.4%), and oppositional behavior (10.9%). The increased vulnerability to psychological problems in children with daytime urinary incontinence underscores the importance of parents seeking early intervention for the condition to help prevent later psychological problems. Moreover, clinicians should be cognizant of the association with

disorders such as ADHD in children with daytime wetting, because this is likely to interfere with treatment success.

Bowel Dysfunction

It has long been recognized that an intimate association exists between both hindgut and LUT function. Indeed, LUTS are seen in approximately 30% of children who present with constipation (Belman and Loening-Baucke, 1998). Previous reports have indicated a significant overlap in these conditions in the primary care setting, with nearly one quarter of children with functional fecal retention also reporting daytime urinary incontinence (Loening-Baucke, 2004). As one would expect, the prevalence of these comorbid conditions is even higher at tertiary care centers. Burgers and associates (2013a) recently reported that nearly half of patients seen at their pediatric urology clinic for LUTS also met criteria for functional constipation.

The relationship between abnormal bowel and bladder activity is termed *bowel-bladder dysfunction (BBD)* and is part of an entity originally described by Koff and colleagues (1998) as the *dysfunctional elimination syndrome*. The International Children's Continence Society discourages using the term *dysfunctional elimination syndrome* as this connotes a particular abnormality or condition (Austin et al, 2014). BBD is a more descriptive comprehensive term that does not necessarily explain pathogenesis but rather encompasses this parallel dysfunction. In any event, Koff recognized the significance of bowel dysfunction; if present, its clear identification and management were paramount if treatment of the LUT condition was to be successful. Koff and colleagues (1998) recommended that each LUT condition be treated specifically while at the same time addressing any concomitant bowel dysfunction, often before treatment of the LUT condition.

Although an exact pathophysiologic basis for BBD has not been clearly elucidated, a number of different theories have been put forth. One theory espouses that rectal distention from fecal retention puts direct pressure on the posterior bladder wall and that this constant force in turn leads to detrusor instability, which can precipitate bladder overactivity and impair efficient bladder emptying (Lucanto et al, 2000). A second theory assumes that both the urethral and anal sphincters share a common neural input. With chronic contraction of the anal sphincter from rectal stool impaction, the pelvic floor musculature similarly contracts inappropriately, leading to secondary detrusor-external urinary sphincter dyssynergia. This vicious cycle of discoordination is what is thought to induce bladder overactivity, urinary incontinence, recurrent UTIs, and VUR (O'Regan et al, 1985).

Please see the Expert Consult website for further details.

KEY POINTS: EPIDEMIOLOGY, SELF-ESTEEM AND QUALITY-OF-LIFE ISSUES AND COMORBIDITIES

- LUTD is commonly encountered in daily practice.
- Daytime incontinence varies with both age and gender in school-age children and seems to be more common in girls.
- There is a clear and consistent relationship between LUTD and UTIs, especially when urinary stasis occurs.
- There is a known association between LUTD and VUR. Continued LUTD is a risk factor for treatment failure after surgical correction for reflux. Targeted treatment for LUTD has been demonstrated to improve spontaneous resolution rates for VUR.
- Clinicians should be cognizant of the association between neuropsychiatric disorders and LUTD. Failure to adequately address these comorbidities is likely to interfere with treatment success.
- The relationship between abnormal bowel and bladder activity is termed *bowel-bladder dysfunction (BBD)*, and, if present, its clear identification and management is paramount if treatment of the LUT condition is to be successful.

In a recent study by [Burgers and colleagues \(2013a\)](#), researchers assessed the prevalence of functional defecation disorders in children referred to a tertiary pediatric urology outpatient clinic for LUTS. They analyzed the records of 113 patients between 4 and 17 years of age who presented with LUTS. Rome III criteria for functional constipation and functional nonretentive fecal incontinence were fulfilled by 47% and 11% of patients with LUTS, respectively. Not surprisingly, children with dysfunctional voiding were more likely to fulfill the criteria for functional constipation, while children with urge incontinence more often fulfilled the criteria for nonretentive fecal incontinence. This last point is intriguing in that it supports the notion that children with fecal incontinence and urge urinary incontinence often will not respond to a standard bowel program, which could potentially exacerbate the situation. Perhaps these children would be better served by a centrally acting agent to aid in suppression of overactivity or lack of inhibition. Clearly, there continues to be a void in our understanding of the bowel and bladder interaction in higher cortical centers and the spinal cord.

In a similar study by [Combs and associates \(2013\)](#), researchers sought to better illuminate the relationship between LUT and bowel dysfunction by studying 368 consecutive children who presented with LUTD. In a secondary analysis, they also sought to determine if constipation and encopresis, which are often presumed to coexist, also coexisted for their specific cohort. Overall, children with dysfunctional voiding had the highest incidence of bowel dysfunction, with constipation alone being the most frequently observed form. Somewhat surprisingly, nearly 50% of patients reporting encopresis did not have associated constipation. The majority of patients with encopresis with or without associated constipation had idiopathic detrusor overactivity, and those with the worst urgency were the ones reporting encopresis. Interestingly, in children with encopresis, severe urgency was commonly reported and after initiation of anticholinergic therapy the encopresis frequently resolved even before the urgency had fully subsided. This finding is similar to the results of [Burgers and colleagues \(2013a\)](#), and perhaps may be secondary to an overactivity of the detrusor and the rectal wall musculature, or a lack of inhibition of detrusor and rectal muscular activity. Whether this is a centrally mediated phenomenon is unclear.

TERMINOLOGY

The International Children's Continence Society (ICCS) is a global, multidisciplinary organization of clinicians involved in the care of children with LUTD (Austin et al, 2014). Perhaps one of the most significant impacts of the ICCS on the pediatric LUT function community was its initial terminology document (Névéus et al, 2006). Before the publication of this document, the nomenclature used in LUTD had been endemic with transposable terms that in some cases were not completely accurate and were often confusing. Moreover, this fostered uncertainty and made it rather difficult to compare research and study outcomes among different groups. The standardization of the nomenclature for pediatric and adolescent LUT function is thus critical in providing a platform for optimal comprehension and more effective interaction and treatment among multiple health care providers who care for these patients. Recently the ICCS revised the original terminology document to provide a current and consensus update reflecting refinement and current advancement of knowledge on pediatric and adolescent LUT function (Austin et al, 2014).

The terminology used for LUTS focuses on descriptive (as opposed to quantitative) language because quantitative data are currently lacking. Of particular relevance is the age of the child when applying terminology to describe pediatric LUT function. The reference point used by the ICCS is 5 years old or greater (4 years of age for bowel dysfunction), because this age is used by the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-V) (American Psychiatric Association, 2013) and the International Classification of Diseases 10 (ICD-10) to characterize urinary incontinence disorders (World Health Organization, 2008). The ICCS terminology document authors do stipulate, however, that there is variability and maturational aspects that certainly will affect LUT function and that there are, in fact, children who have voluntary control over LUT function under 5 years of age. As a result, it is at the discretion of the provider to selectively apply these terms in younger cohorts of children. (See "Terminology Document" by Austin and associates, 2014, for specific terms and their definition.)

DAYTIME URINARY INCONTINENCE AND BLADDER DYSFUNCTION

Evaluation

Evaluation of the child or adolescent with suspected voiding dysfunction commences with a detailed and thorough history and physical examination. The goals of evaluation are first and foremost to determine whether the patient has a filling or emptying (or both) phase abnormality. If an abnormality is found, the evaluation should then be directed toward determining the underlying cause and distinguishing whether the dysfunction stems from an anatomic or functional issue. This last point is critical because the management strategy will depend on the cause.

History

A thorough history is going to be invaluable in ascertaining whether and what type of bladder dysfunction is present. In general, the history should be taken from the child if possible (as opposed to caregivers) and tailored to the maturational age and stage of development of bladder and bowel control. Our approach has been to first focus on the identification of a possible anatomic or neurologic source to explain a patient's current symptomatology and, once this has been ruled out, to distinguish which form of bladder dysfunction is present. Vital components of the history often will include voiding schedule, symptomatology, bowel habits, family history, maternal prenatal history, perinatal history, developmental milestones, toilet training, neuropsychiatric comorbidities, medical/surgical history, social history, diet, and previous UTIs.

Bladder and Bowel Diaries

Perhaps one of the most helpful diagnostic tools in the armamentarium of providers who care for children with LUTD is the voiding diary. Its usefulness stems from the fact that this log is an objective record of the child's bowel habits and urinary voiding pattern. The diary should include voided volumes, timing of each void and incontinent episode, timing of each bowel movement and fecal soiling episode, and fluid intake.

In the evaluation of LUTD, the frequency/volume chart is a diary recording fluid intake and urine output during a 24-hour period (Bower et al, 1997; Hoebeke et al, 2010). It can be used for both diagnostic and therapeutic purposes. For diagnostic purposes, the chart should cover at least 48 hours and not necessarily recorded on 2 consecutive days (Austin et al, 2014). Episodes of urgency and urine loss also should be recorded. Urine loss is quantified by recording if clothing had to be changed after the urine loss (significant urine loss) or not. The chart gives information about fluid intake, number of voids, voided volume, and urine loss (Fig. 143-1). We also employ a 7-day bowel diary that uses the Bristol Stool Form scale (Lane et al, 2011) in ruling out BBD. Although controversy surrounds the best way to diagnose functional constipation in children, the ICCS recommends the use of the Rome III criteria (Rasquin et al, 2006).

Questionnaires

Questionnaires in the evaluation of LUT function have emerged as useful tools to more objectively translate somewhat subjective complaints into semiquantitative data (Akbal et al, 2005). These scoring systems not only allow providers to more accurately gauge the extent of LUTD but also provide a method of monitoring outcomes during treatment (Afshar et al, 2009). The two main types of questionnaires that have emerged for pediatric LUTD are measurements of LUT function and psychological screening.

Dysfunctional Voiding Symptom Score

In 2000, Farhat and colleagues (2000) reported on the creation of the DVSS based on the International Prostate Symptom Score for benign prostatic hyperplasia. The DVSS was the first scoring system of its kind and has been used in a variety of clinical settings. There are 10 quantitative and qualitative urologic parameters translated into age-appropriate questions for children regarding urinary symptoms, such as urinary incontinence, voiding habits, urgency, posturing, bowel habits, and stressful life conditions. The 10 questions were assigned scores of 0 to 3 according to incidence in the month before responding to the questionnaire and responses are weighted equally, giving a maximum possible score of 30 (Fig. 143-2).

Pediatric Urinary Incontinence Quality of Life Score

The Pediatric Urinary Incontinence Quality of Life Score (PIN-Q), developed by Bower and colleagues (2006b) measures the emotional impact that urinary incontinence has on a child. This cross-cultural urinary incontinence quality-of-life tool has been found to have excellent test-retest reliability and validity (Bower et al, 2006a). It consists of 20 questions related to urinary incontinence quality of life that are graded on a scale of 0 to 4 (0 = No, 1 = Hardly ever, 2 = Sometimes, 3 = Often, 4 = All the time) with a total possible score of 80. The total score indicates the impact urinary incontinence has on the child's quality of life, with the higher score indicating a more significant effect. Both the PIN-Q and DVSS questionnaire have been found to be complementary and provide a clinically appropriate picture of LUTD and its impact on a child's quality of life (Thibodeau et al, 2013).

Psychological Screening

It is well documented that children with BBD have a high rate of comorbid behavioral and emotional disorders. In several

Figure 143-3. Occult spina bifida in a child with a sacral dimple. (Courtesy Elaine Fonseca, MD.)

(Fig. 143-3). These include an asymmetrical gluteal cleft, a presacral dimple, a lipoma, a hair tuft, a dermal sinus tract, and a dermal vascular malformation. In general, these lesions should be evaluated with magnetic resonance imaging of the lumbar and sacral spine.

Genital Examination

In boys, the examination necessarily includes inspection of the urethral meatus to detect possible meatal stenosis. Although direct inspection of the meatus may be sufficient, our preference has been to observe the urinary stream directly during voiding to note its caliber and direction because this entity is not a true stenosis but rather a ventral urethral membrane that deflects the urinary stream upward (Fig. 143-4). Almost invariably, meatal stenosis is seen in circumcised boys because the prepuce is thought to protect the meatus from chronic irritation and subsequent epithelialization of this ventral meatal web of tissue. Epididymoorchitis sometimes can be seen in males with dyssynergic voiding. The theory is that increased bladder pressures can lead to retrograde reflux of caustic urine into the ejaculatory ducts, leading to inflammation along the course of the vas deferens, epididymis, and testes.

In girls, deformities of the urethral meatus also have been noted to be associated with LUT voiding dysfunction (Hoebeke et al, 1999; Klijn et al, 2012). The theory is that girls with certain anomalies of the urethral meatus (i.e., a ventral web of tissue akin to meatal stenosis in males) predispose to an anterior deflected urinary stream and so they cannot void in the ideal toileting position. This then results in lower success rates for behavioral training programs. Hoebeke and colleagues (1999) demonstrated that young females with meatal deformities were diagnosed with more severe forms of dysfunctional voiding on urodynamic investigation compared to a control group. They also showed improved micturition patterns and fewer symptoms after surgical correction. This finding

Figure 143-4. Meatal stenosis with an inferior web of tissue that results in an upward urinary deflection.

was corroborated in a second study by [Klijn and associates \(2012\)](#), who found that 39% of female patients with dysfunctional voiding reported an anteriorly deflected urinary stream. After surgical correction, they found that half of these girls were free of all related symptoms and required no further behavioral training. Examination of the labia and vaginal introitus is performed to detect any evidence of labial adhesions. Although labial adhesions are often purported to be a cause of bladder outlet obstruction (BOO), this has rarely been the case in our experience, unless they are dense enough to require surgical division. More often, as the labia minora adhere (usually from posterior to anterior) the resultant pouch sequesters small amounts of urine that may dribble into the underwear between voids, depending on the child's posture. The stagnant urine in the pouch predisposes to asymptomatic bacteriuria and UTI ([Leung and Robson, 2004](#)). The problem is usually self-limited at around the time of puberty because the presence of estrogen has a protective effect ([Leung and Robson, 2004](#)). Areas of skin excoriation or redness may be present and are often a sign of continuous or severe urinary leakage with chronic inflammation and less often secondary to fungal infection.

Neurologic Examination

A focused neurologic examination should include assessing lower extremity strength and deep tendon reflexes, gait, perineal and anal sensation, and rectal tone. The anocutaneous reflex (i.e., "anal wink") and bulbocavernosus (Osinski) reflex should be assessed to denote any interruption of the sacral reflex arcs (S2 to S4). Any abnormality of the neurologic examination may be indicative of a neurologic lesion that also affects the function of the bladder and should be assessed with proper spinal imaging.

Investigative Tools

Urinalysis

The single most important and perhaps only laboratory test that should be performed in all children who present with LUTD is the urinalysis. This screening test will invariably aid in deciphering whether the child's symptomatology is due to a bona fide UTI or is merely dysuria associated with BBD. **Particularly important elements of the urinalysis include specific gravity and the presence of white or red blood cells, bacteria, protein, and glucose.** A low specific gravity may be secondary to a renal concentrating defect and often will lead to polyuria. White blood cells (WBCs) suggest infection and/or inflammation. Red blood cells (RBCs) generally denote infection when found with WBCs; however, isolated RBCs can be found in children with LUTD secondary to storage and

voiding dynamics. Isolated proteinuria is common in children and may represent a benign condition or a serious underlying renal disease or systemic disorder. Depending on the degree of proteinuria, consideration should be given to obtaining a serum creatinine level to estimate the glomerular filtration rate. Significant glucosuria clinches the diagnosis of diabetes mellitus and often will lead to significant polyuria.

Urine Culture and Sensitivity

A urine culture sample should be obtained if there is evidence of a bona fide UTI. We generally would not recommend performing urine cultures reflexively on all patients, because this practice will undoubtedly identify patients with simple bacterial colonization and has the potential to foster bacterial resistance and infection with more virulent organisms if treated.

Uroflowmetry

Uroflow studies consist of measuring the velocity of urinary flow (volume voided per unit time) and examining the pattern during urination into a uroflowmeter. The child voids into a collection device that produces a urinary flow curve providing the maximum (Qmax) and average (Qavg) urinary flow rates, voided volume, flow time, and shape of urine flow. Uroflowmetry may be done concomitantly with electromyography (EMG) testing of the pelvic floor musculature and external urethral sphincter by affixing pads to the perineum. **The advantage of combining EMG with uroflowmetry is the ability to appreciate synergy or dyssynergy between the bladder and the pelvic floor-sphincter complex.**

Qmax is the most relevant quantitative variable when assessing bladder outflow. Sharp peaks in the curve are usually artifacts, so maximum flow rate should be registered only when a peak level has a duration of longer than 2 seconds ([Szabo et al, 1995](#)). In studies of normal children and adults, a linear correlation has been found between maximum flow and the square root of voided volume ([Chang et al, 2013](#)). If the square of the maximum flow rate ($[mL/s^2]$) equals or exceeds the voided volume (milliliters), the recorded maximum flow is most likely normal.

There are a few caveats that should be mentioned. **First, to obtain an interpretable uroflow, a child must be toilet-trained.** **Second, uroflowmetry provides information regarding the emptying phase of the bladder only and gives no information about what is happening during filling.** **Third, it is important that the volume of voided urine is adequate, because curves change when the voided volume is less than 50% of expected bladder capacity for age** ([Austin et al, 2014](#)). Finally, it is critical to obtain more than one curve to improve the accuracy, reliability, and interpretation of the test.

Uroflowmetry provides readily useful information regarding the pattern or shape of urine flow curve that often can be diagnostic of an underlying cause. In fact, obtaining an adequate uroflow pattern along with a coherent history and physical examination often can obviate the need to pursue more invasive urodynamic testing, which should be performed only when the diagnosis is unclear. The precise shape is determined by detrusor contractility and influenced by abdominal straining, coordination with the bladder outlet musculature, and any anatomic obstruction. The ICCS has developed categories for what is considered normal and abnormal, with five types of urine flow patterns identified ([Fig. 143-5](#)). Each specific pattern is no guarantee of an underlying diagnostic abnormality but rather serves as a guide to the existence of a specific condition.

Bell-Shaped Curve. The urinary flow curve of a healthy child should register as a smooth *bell-shaped* curve regardless of gender, age, and voided volume.

Tower-Shaped Curve. The tower-shaped curve is a sudden, high-amplitude curve of short duration that suggests an OAB produced by an explosive voiding contraction. It should be noted, however, that children with OAB may have a bell-shaped curve because this LUTD is mainly related to the filling phase of the bladder.

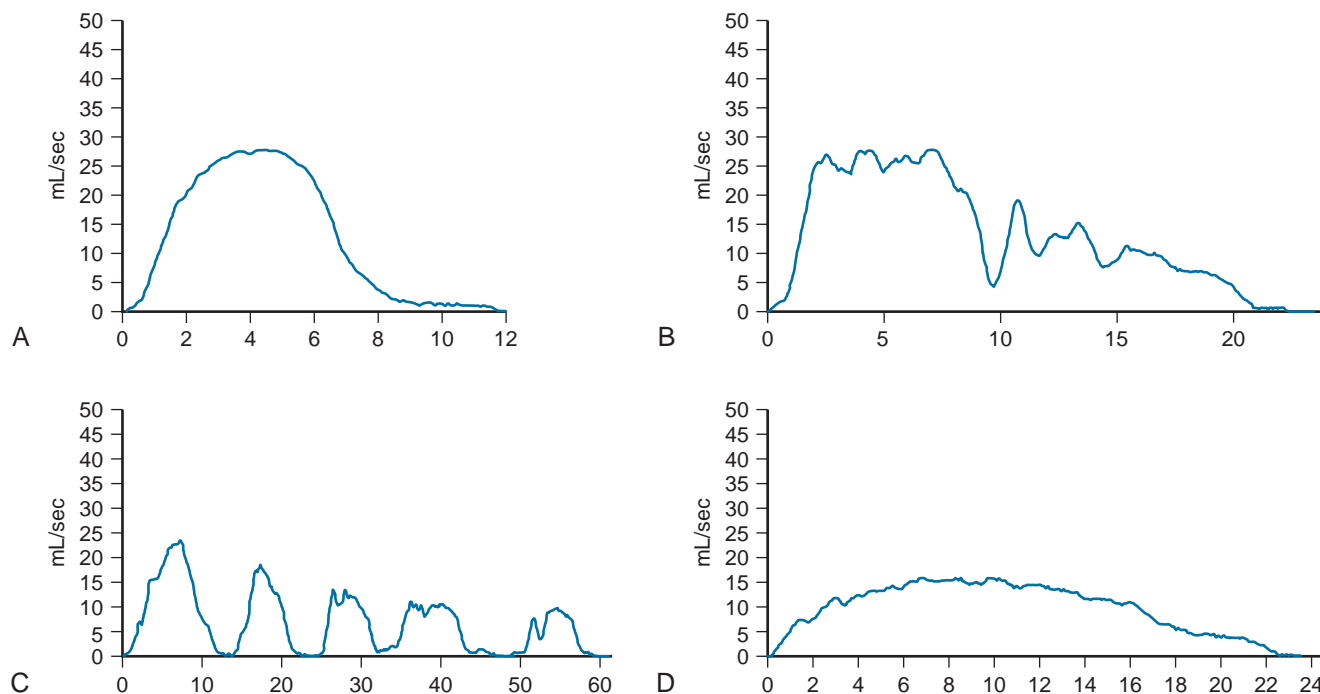

Figure 143-5. Common uroflow patterns. A, Bell shaped. B, Staccato. C, Interrupted. D, Plateau. (From Austin PF, Bauer SB, Bower W, et al. The standardization of terminology of lower urinary tract function in children and adolescents: update report from the Standardization Committee of the International Children's Continence Society. *J Urol* 2014;191:1863-5.)

Staccato-Shaped Curve. The staccato-shaped pattern is irregular and fluctuating throughout voiding, but the flow is continuous and never reaches zero during voiding. This pattern suggests intermittent sphincter overactivity during voiding and is often associated with dysfunctional voiding. It will be seen as sharp peaks and troughs in the flow curve. To qualify for a staccato label, the fluctuations should be larger than the square root of the maximum flow rate.

Interrupted-Shaped Curve. This flow curve will display discrete (albeit low amplitude) peaks similar to a staccato-shaped curve; however, there will be segments where the flow rate is zero with complete cessation of urinary flow between these peaks. This flow pattern suggests an underactive bladder because each peak represents abdominal muscle straining (i.e., Valsalva) creating the main force for urine evacuation. In between each strain, the flow ceases as a result of an absent or weak detrusor contraction. It is possible this flow pattern can be seen with dyssynergy between the bladder and external urethral sphincter, and a concomitant EMG and/or pressure flow study often will be useful to distinguish between the two.

Plateau-Shaped Curve. The plateau-shaped curve is a flattened, low-amplitude prolonged flow curve that is suggestive of BOO. The BOO can be anatomic (e.g., posterior urethral valves or urethral stricture) or dynamic (e.g., continuous, tonic sphincter contraction). Flow EMG may differentiate among BOO subtypes. A plateau-shaped curve may be seen with an underactive bladder during a long continuous abdominal strain. Abdominal pressure monitoring during the uroflow can help delineate an underactive bladder condition.

Pelvic Ultrasound

Pelvic ultrasound is a key tool in the evaluation of pediatric LUT function and is used in the initial evaluation of all children with suspected BBD at our institution (Fig. 143-6). In addition to giving objective information about the voiding pattern of the child in question, it can be readily used to monitor progress over time.

Figure 143-6. Pelvic ultrasound demonstrating a thickened bladder wall and a large amount of stool in the rectum.

Ultrasonography can calculate bladder volume and thus is useful in measuring prevoid and postvoid residual (PVR) urine volume and anatomic details of the bladder and rectum (e.g., bladder wall thickness, stool, rectal distention).

Postvoid Residual

PVR measurements in neurologically intact children are highly variable with significant intraindividual variability. Chang and Yang (2009) suggested that abnormal PVR urine volume could be defined as a PVR greater than 20 mL (as opposed to >10% of estimated bladder capacity) on repeat micturitions without bladder

overdistention. Recently, investigation of 1128 healthy Taiwanese children between 4 and 12 years of age with a bell-shaped uroflow pattern and a voided volume of greater than 50 mL support the following normative 95th percentile values for an abnormally elevated PVR (Chang et al, 2013):

- **Children 4 to 6 years:** Single PVR greater than 30 mL or greater than 21% of bladder capacity (BC), where BC is determined as voided volume (VV) + PVR and expressed as percent of the expected bladder capacity ($EBC = [age\ (yr) + 1] \times 30\ mL$). It is recommended that a repeat PVR be performed with dual measurements; a repetitive PVR greater than 20 mL or greater than 10% BC is considered significantly elevated.
- **Children 7 to 12 years:** A single PVR greater than 20 mL or 15% BC or repetitive PVR greater than 10 mL or 6% BC is considered elevated.

According to Chang and colleagues (2013), standard conditions should be applied to measuring PVR; the bladder should not be underdistended (<50%) nor overdistended (>115%) in relation to the EBC; PVR must be obtained immediately after voiding (<5 minutes). Further validation is needed for these nomograms in similar cohorts across cultures.

Bladder Wall Thickness

In daily clinical practice a thickened bladder wall should alert the clinician to long-standing problems with urine storage and emptying. The bladder wall is normally less than 3 mm when full and less than 5 mm when relatively empty (Jequier and Rousseau, 1987). A thickened bladder wall is suggestive of an anatomic or functional outlet obstruction causing detrusor hypertrophy; however, the most common diagnosis associated with a thickened bladder wall was found to be OAB (Yeung et al, 2007). Bladder wall thickness can be measured with either a full or an empty bladder and is inversely proportional to the degree of bladder filling.

Please see the Expert Consult website for further details.

Rectal Distention

Although there is insufficient evidence to support the notion that the transverse diameter of the rectum alone can be used as a predictor of constipation and fecal impaction, a number of authors have made several observations on this subject (Fig. 143-7). Klijn and associates (2004) measured the diameter of the rectum on bladder ultrasonography in a constipated group of patients with dysfunc-

Figure 143-7. Pelvic ultrasound showing a dilated rectum filled with stool compressing posterior wall of bladder.

tional voiding and compared this diameter in a control group of patients with a normal defecation pattern. Not surprisingly, in the group of constipated patients with dysfunctional voiding, the diameter of the rectum was significantly larger than in the control group.

Please see the Expert Consult website for further details.

Bristol Stool Scale

The Bristol Stool Scale or Bristol Stool Chart is a useful guide designed to classify the form of human feces into seven distinct categories. Sometimes referred to in the United Kingdom as the Meyers scale, it was developed at the University of Bristol in 1997 (Lewis and Heaton, 1997). The seven types of stool (ranging from most firm in type 1 to loosest in type 7) are as follows (Fig. 143-8):

- **Type 1:** Separate hard lumps, like nuts (difficult to pass because stool has not retained any water)
- **Type 2:** Sausage-shaped, but lumpy; represents multiple type 1 stools congealed into a single mass, typical for functional constipation
- **Type 3:** Like a sausage but with cracks on its surface
- **Type 4:** Like a sausage or snake, smooth and soft, typical for someone who has a daily bowel movement
- **Type 5:** Soft blobs with clear-cut edges, passed easily, usually multiple times per day
- **Type 6:** Fluffy pieces with ragged edges, a mushy stool, urge to defecate can be difficult to control
- **Type 7:** Watery, no solid pieces, entirely liquid

We prefer to use it as a clinical communication aid with our patients and their families in terms of what to strive for and to facilitate titration of supplemental fiber or laxative administration.

BRISTOL STOOL SCALE		
Type 1		Separate hard lumps, like nuts (hard to pass)
Type 2		Sausage-shaped but lumpy
Type 3		Like a sausage but with cracks on its surface
Type 4		Like a sausage or snake, smooth and soft
Type 5		Soft blobs with clear-cut edges (passed easily)
Type 6		Fluffy pieces with ragged edges, a mushy stool
Type 7		Watery, no solid pieces. Entirely liquid

Figure 143-8. Bristol Stool Chart. (Modified from Lewis SJ, Heaton KW. Stool form scale as a useful guide to intestinal transit time. Scand J Gastroenterol 1997;32:920-4.)

In 2004, Yeung and colleagues reported on their evaluation of a special bladder ultrasound protocol for the assessment of LUTD compared with urodynamic findings and for the prediction of treatment outcome in children with enuresis (Yeung et al, 2004b). The bladder volume wall thickness index (BVWI) was a ratio of bladder volume to wall thickness, and they found statistically significant correlations between BVWI and enuresis treatment response. In addition, there was a high predictive value of normal bladder function as evaluated by urodynamics with a normal BVWI. Although it is intuitive that bladder wall thickness would correlate with LUTD, not all groups have come to the same conclusion (Mostafavi et al, 2012).

Recently, Burgers and colleagues (2013b) took a group of 84 children with a median age of 9 years (range 6 to 11) and performed both transabdominal ultrasound and digital rectal examination (DRE) under anesthesia. A rectal mass was found on transabdominal ultrasound and DRE in 32% and 41% of all children, respectively, with agreement between the two tests in 82.5%. The median diameter of the rectum was 3.3 cm in children with a full rectum and 2.5 cm and 2.0 cm in patients with a half-filled and empty rectum, respectively. They concluded that transabdominal ultrasound was a noninvasive and reliable alternative to assess the rectal filling state and might replace DRE in the evaluation of children with constipation.

KEY POINTS: EVALUATION OF DAYTIME URINARY INCONTINENCE AND BLADDER DYSFUNCTION

- The goals of evaluation are to determine whether the patient has a filling or emptying (or both) phase abnormality. If an abnormality is found, the evaluation then should be directed toward determining the underlying cause and distinguish whether the dysfunction stems from an anatomic or functional issue.
- Vital components of the history include voiding schedule, symptomatology, bowel habits, family history, maternal prenatal history, perinatal history, developmental milestones, toilet training, neuropsychiatric comorbidities, past medical/surgical history, social history, diet, and previous UTIs.
- The voiding diary is one of the most helpful diagnostic tools in the armamentarium of providers who care for children with LUTD.
- During physical examination, special attention should be paid to the lower back for cutaneous manifestations of occult spinal dysraphism.
- All children presenting with LUTD should provide a urinalysis with important elements of the urinalysis, including the specific gravity and the presence of white or red blood cells, bacteria, protein, and glucose.
- Uroflowmetry provides readily useful information regarding the pattern or shape of urine flow curve that can often be diagnostic of an underlying cause. Qmax is the most relevant quantitative variable when assessing bladder outflow.
- Ultrasonography can calculate bladder volume and thus is useful in measuring prevoid and PVR urine volume and can provide useful anatomic details of the bladder and rectum (e.g., bladder wall thickness, stool presence, rectal distention).

Treatment

The ICCS has published treatment guidelines on various LUT conditions and their associated comorbidities (Chase et al, 2010; Hoebeke et al, 2010; Franco et al, 2013; Burgers et al, 2013c; Austin et al, 2014). The management of a child or adolescent who suffers from LUTD is primarily directed at improving symptoms (e.g., urinary and/or fecal incontinence, recurrent UTIs) and protecting the upper urinary tract from permanent damage. Methods for treating children with BBD must be tailored to the specific LUTD and the child's symptomatology. Therapeutic considerations include the underlying cause, patient age, motivation and maturity level, symptom severity and duration, prior interventions, and potential risk factors for upper urinary tract damage (i.e., elevated intravesical storage pressures, VUR, recurrent UTIs).

We use a stepwise approach to the treatment of children presenting with symptoms concerning for BBD (Thom et al, 2012). Our algorithm generally moves from least to most invasive with conservative measures (e.g., treatment of constipation, behavioral modification) exhausted before initiating medications, physical therapy, biofeedback, neuromodulation, or surgical intervention.

According to the ICCS, researchers and/or clinicians should recognize three basic principles of treatment outcomes (Austin et al, 2014). First, the symptom frequency during baseline and after treatment should each be documented. Second, the assessment of treatment response must be based on pretreatment baseline registration symptom frequency. Third, the response during treatment should be noted, as well as the response after cessation of treatment for a specified period; and these two responses may not be the same. This has been outlined as follows:

- **Initial success** (based on symptom frequency)
 - No response: Less than 50% reduction
 - Partial response: 50% to 99% reduction
 - Complete response: 100% reduction

- **Long-term success**

- Relapse: More than one symptom recurrence per month
- Continued success: No relapse in 6 months after cessation of treatment
- Complete success: No relapse in 2 years after cessation of treatment

Urotherapy

Urotherapy is conservative-based therapy and treatment of LUTD that rehabilitates the LUT and encompasses a very wide field of health care professionals (Austin terminology document [Austin, 2014]). It primarily involves behavioral modification of voiding (i.e., timed voiding schedules), lifestyle modifications, and treatment of constipation. Although there are no randomized, controlled trials comparing the efficacy of conservative intervention to other therapies, several retrospective studies suggest a reduction in symptoms of up to 70% with a strictly conservative approach (Wiener et al, 2000; Allen et al, 2007).

Urotherapy can be divided into standard therapy and specific interventions. **Standard components** include the following:

1. *Information and demystification.* It is often helpful to explain normal LUT function to parents and children and how the particular child deviates from normal.
2. *Instruction* on how to resolve LUTD (i.e., behavioral modification, timed voiding, treatment of constipation).
3. *Lifestyle advice.* Encompasses balanced fluid intake and diet modification; diminished dietary irritants such as caffeine, carbonation, citrus, chocolate, and spicy foods; regular bladder and bowel emptying patterns; and skin care for those with perineal irritation from incontinence. It is also helpful to review optimal posture during voiding (i.e., sitting in the middle of the toilet with heels flat on the ground or supported on a footstool). One useful aid to teach correct upright posture is to have children straddle the toilet seat and face the toilet bowl during voiding, because this spreads the legs apart (preventing holding maneuvers such as forcefully crossing the legs) and forces them to straighten the back as they balance themselves on the toilet seat. This maneuver also can be used to successfully correct vaginal reflux.
4. *Registration* of symptoms and voiding habits, using bladder diaries or frequency-volume charts and potentially mobile applications.
5. *Support and encouragement* via regular follow-up with the caregiver.

Specific interventions of urotherapy include various forms of pelvic floor muscle retraining (i.e., biofeedback), neuromodulation, and intermittent catheterization.

Conservative Management

Bowel Dysfunction

One of our first steps is to decipher whether concomitant bowel dysfunction exists based on history, physical examination, and pelvic ultrasound. As mentioned previously, anorectal and LUT function are closely interrelated. If evidence of bowel dysfunction is indeed present (as is often the case), we generally initiate a bowel regimen that includes high fiber and increased fluid intake. Our rule of thumb for daily fiber intake is age in years + 15 to 20 for total number of grams to be ingested. Parents are reminded that without concurrent increased fluid intake, increased fiber could actually make matters worse by allowing smaller stool balls to bind together and subsequently increase the severity of their child's constipation.

If increased fiber is not a feasible solution, we usually recommend titrating polyethylene glycol such that children are eventually having daily Bristol type 4 stools. In severe cases, we recommend a complete bowel cleanse (i.e., chemical disimpaction) consisting of what we term "magic mousse" supplementing with tap water enemas to relieve any distal obstruction by impacted stool in the

rectal vault. Magic mousse consists of three simple ingredients: 1 cup ice cream, 1 cup prepared pudding, 6 oz. mineral oil, that are mixed and frozen (Campigotto, personal communication, 2014). Children younger than 6 years of age are given 4 T twice daily and those 6 years of age or older get double the dose twice daily. This is generally done over a weekend for children who are in school or daycare because this routine is fairly intense and children may have multiple, somewhat unpredictable bowel movements. **It is imperative that the bowel regimen be continued throughout the treatment course to both maximize therapeutic efficacy for the bladder dysfunction component and counteract the constipating side effect of anticholinergic medications.**

The importance of addressing constipation in those with BBD is substantiated by the findings of a large retrospective study of 234 chronically constipated and encopretic children who were treated for constipation and reassessed at least 12 months after initiation of therapy (Loening-Baucke, 1997). Of these children, 29% complained of daytime urinary incontinence and 34% had enuresis. UTI was present in 11% of the cohort and was more common in girls. **Relief of constipation resulted in disappearance of daytime urinary incontinence in 89% and enuresis in 63% of patients. There were no reported UTIs in any patient who had no anatomic abnormality of the urinary tract.**

Behavioral Modification

The ultimate goal of any structured behavioral modification program is to return the child to normal micturition habits. With this goal in mind, it is important to set an individualized voiding regimen to establish a consistent voiding routine. **The classic regimen entails timed voiding with frequent voids scheduled every 2 hours during the day.** This strategy is crucial in aiding to avoid bladder overactivity and urge symptoms, which can occur as the bladder fills and begins to reach the critical volume that triggers the urge to void. We recommend wristwatch alarms to all patients because these can readily assist older, more independent children to comply with timed voiding (Hagstroem et al, 2010). The use of a vibratory watch is also a good option because it does not disturb peers, with only the patient knowing that it has indicted the set time. Regardless of what regimen is used, children are encouraged to urinate before they have a sense of urgency, empty their bladders completely, and avoid abdominal straining.

The timed voiding regimen is often linked to a positive reinforcement program using a diary in which the child tracks the number of times voided during the day. It has been demonstrated that the establishment of a reward system can significantly improve the child's self-esteem and compliance (Allen et al, 2007). Specifically, the incentive scheme should focus on rewarding the child for following the recommended program (e.g., stickers each time the child voids during the day) as opposed to "not wetting" themselves. Not surprisingly, behavioral modification has been shown to be more successful in older children (older than 8 years of age), who, in general, will be more motivated by peer pressure and are mature enough to respond to and follow instruction (Curran et al, 2000; Heilenkötter et al, 2006).

Biofeedback

Biofeedback is a treatment modality that uses electronic or mechanical instruments to relay perceptual evidence to assist a person in gaining control over a physiologic process or function (Liberati, 2005). This method has been used for over three decades in the urologic setting and employs noninvasive urodynamic instrumentation to measure, record, and provide direct, instantaneous information to the child about voiding function (Maizels et al, 1979). Real-time uroflowmetry allows the patient to observe the urine flow rate. Concurrent placement of adhesive pads on the perineum measures sphincter and/or pelvic floor activity. Abdominal EMG also can be performed if desired. Each session lasts approximately 45 minutes with a trained practitioner overseeing therapy. The visual and auditory feedback allows the child to become aware of and gain

control over LUT function by teaching them how to voluntarily relax their sphincter and pelvic floor musculature during voiding, thus preventing detrusor-sphincter dyscoordination. In fact, many biofeedback programs have been tailored to children by using interactive computer games controlled by pelvic floor contraction and relaxation along with urinary flow rate (McKenna et al, 1999). This system has facilitated the training process and lowered the age at which children can be successfully treated; however, one should bear in mind that most children under 5 years of age are typically incapable of receiving biofeedback regularly.

A number of observational studies have documented the utility of biofeedback therapy in reducing the symptoms associated with LUTD (Yamanishi et al, 2000; Chin-Peuckert and Salle, 2001; Nelson et al, 2004; Klijn et al, 2006), expediting the resolution of VUR (Palmer et al, 2002; Kibar et al, 2007), and eliminating recurrent UTIs (Nelson et al, 2004). Recently, a systematic review evaluated the efficacy of biofeedback in the treatment of children with BBD (Desantis et al, 2011). The review included 27 studies (1 randomized controlled trial and 26 case-series). The pooled estimate showed an 83% and 80% improvement in UTI and daytime urinary incontinence, respectively. The only included randomized study favored biofeedback over standard urotherapy (relative risk [RR] 1.4, 95% confidence interval [CI] 0.98 to 2), but this was not statistically significant. On analysis of all included studies, there also was improvement in constipation (18% to 100%), frequency (67% to 100%), urgency (71% to 88%), and VUR (21% to 100%).

Clean Intermittent Catheterization

Lapides and colleagues (1972) first introduced the concept of clean intermittent catheterization (CIC) as a method of emptying the bladder in neurologically impaired patients. Since its initial description, this treatment strategy has gradually been employed in neurologically intact individuals with various types of LUTD. In the setting of dysfunctional voiding and in children who postpone micturition, the detrusor muscle stretches and the bladder becomes chronically overdistended. This repeated action over time can lead to underactive bladder with the end result of myogenic failure. In these cases, bladder emptying is often incomplete, resulting in large PVR urine volumes, urinary incontinence, and recurrent UTIs from stasis. CIC is a safe, effective, and well-tolerated treatment strategy to attain continence and reduce the rate of recurrent UTI in children with LUTD (Pohl et al, 2002). It is particularly crucial to discuss the merits of this intervention with sensate patients and their families to maximize adherence.

Pharmacotherapy

Pharmacologic intervention in the treatment of children with LUTD has traditionally encompassed anticholinergic agents and α -adrenergic receptor antagonists (i.e., α -blockers) to enhance bladder filling and emptying, respectively. We will generally initiate one or both of these two medications once all other conservative measures have been exhausted. In some instances we will start α -blockers concomitantly with biofeedback, and this management decision is ultimately left up to the discretion of the provider.

Anticholinergic Agents

Anticholinergics (i.e., antimuscarinics) are the current gold standard in the treatment of patients with symptoms referable to OAB. Muscarinic receptors are found in the human detrusor muscle, and bladder contractions are initiated by stimulation of these receptors with the release of acetylcholine from cholinergic nerves. The main action of anticholinergics is on the M1 and M3 receptor subtypes, which are thought to be responsible for the pathogenesis of detrusor overactivity (Chapple et al, 2002). **These agents act by reducing the frequency and intensity of uninhibited detrusor contractions during the filling phase of the bladder, resulting in an increase in the functional bladder capacity and compliance (Nijman, 2004; Finney et al, 2006).** The clinical efficacy depends

on various factors such as receptor affinity, pharmacokinetics, and the specificity for the bladder.

Oxybutynin was among the first generation of modern antimuscarinic medications available for treating incontinence in children. Five anticholinergic agents are currently approved in the United States for the treatment of OAB (darifenacin, oxybutynin, solifenacin, tolterodine, and trospium), with only two of these (oxybutynin and tolterodine) having formally achieved approval for use in children. Oxybutynin has antimuscarinic, antispasmodic, and analgesic properties. It causes the antispasmodic effect by acting as a calcium channel blocker. The analgesic and antispasmodic properties make the medication particularly attractive; however, these effects occur only with supraphysiologic doses that would render them useless secondary to side effect profile (Chapple, 2000).

The nonselective pattern of activity and penetration of the blood-brain barrier are known to induce systemic and central side effects, respectively. The longer acting extended-release formulation (Oxybutynin XL) is also approved by the U.S. Food and Drug Administration (FDA) for use in children and uses a novel delivery system resulting in absorption in the large intestine (Youdim and Kogan, 2002). This avoids the first-pass metabolism in the liver, leading to a decrease in the active metabolite *N*-desethyloxybutynin, thought to be responsible for many of the adverse effects associated with the use of oxybutynin. **The main side effects include constipation, dry mouth, blurred vision, reduced sweating, flushing, and altered behavior and cognition.** Oxybutynin is lipid soluble and therefore likely to cross the blood-brain barrier and in adults has been reported to interfere with cognition. However, in a non-randomized trial of 25 children, Sommer and colleagues (2005) found that treatment with oxybutynin was not associated with cognitive impairment. Additionally, in a recent study by Veenboer and associates (2013), no significant differences in behavior were found between children with spinal dysraphism with and without long-term use of antimuscarinics.

Other methods of delivery of oxybutynin are intravesical and transdermal. The intravesical method of delivery avoids the first-pass effect and leads to increased amounts of oxybutynin available compared to immediate-release oral oxybutynin. Its use in the non-neurogenic, sensate population is limited, however, because of the need for catheterization. **The transdermal patch is as efficacious as the immediate-release oral form but with nearly half the incidence of dry mouth (Davila et al, 2001).** Local skin erythema and pruritus are side effects unique to this route of administration that can be seen in over one third of patients (Gleason et al, 2014).

α-Adrenergic Receptor Antagonists (α-Blockers)

α-Adrenoreceptors have been demonstrated in the LUT, with a large concentration located at the bladder neck and urethra (Ek, 1978). **α-Adrenergic blockade results in smooth muscle relaxation and decreased bladder outlet resistance.** Limitations of early α-blockers included their side effect profile with hypotension and dizziness. With subsequent development of more “selective” α-blockers in the 1980s that targeted α_{1a}-receptors rather than both α_{1a}- and α_{1b}-adrenergic receptors, these side effects were greatly diminished. Examples of selective α-blockers include alfuzosin, doxazosin, prazosin, silodosin, tamsulosin, and terazosin.

Currently, α-blockers are a mainstay drug used to facilitate bladder emptying in the adult population, particularly in adult males with benign prostatic hyperplasia. Early work on the benefits of α-blockers on pediatric LUTD by Austin and colleagues (1999) pioneered the introduction of α-blockers into the armamentarium of drugs that can be used to treat voiding issues in children. In this pilot report, there was an 82% improvement in the measured parameters of 17 patients treated with α-blocker therapy. In a follow-up of their initial study, the group continued to see improvement in multiple LUTS, daytime incontinence episodes, and PVR measurements in 55 children treated with doxazosin for dysfunctional voiding (Cain et al, 2003).

Please see the Expert Consult website for further details.

α-Blocker treatment selection of children with LUTD is done through a comprehensive treatment program that involves an escalating treatment paradigm (Chase et al, 2010; Thom et al, 2012) or by identifying patients with characteristic uroflow abnormalities (Van Batavia et al, 2010). The uroflow finding of a prolonged “EMG lag time” is associated with bladder neck and internal urethral sphincter discoordination and may be used to select patients for α-blocker therapy (Van Batavia et al, 2011, 2014). The EMG lag time is the time duration after the external sphincter relaxes and the flow of urine. A prolonged lag time of greater than 6 seconds is suggested as a reliable indicator of tailoring LUTD treatment with α-blocker therapy (Van Batavia et al, 2014). Further validation is needed to investigate the reliability and reducibility of these uroflow findings.

Botulinum Toxin

A relatively recent investigational pharmacologic approach in refractory cases of LUTD is botulinum-A toxin (BTX-A). The toxin acts by inhibiting acetylcholine (ACh) release at the presynaptic neuromuscular junction. Inhibited ACh release results in regionally decreased muscle contractility and atrophy at the injection site. The chemical denervation that ensues is a reversible process, and eventually the toxin is inactivated and removed. Clinical effects begin within 5 to 7 days of injection with maximal effects reached within 4 to 6 weeks (Game et al, 2009). The duration of induced paralysis varies depending on the type of muscle treated, with duration of treatment effect lasting between 3 and 12 months (Riccabona et al, 2004).

Clinically, BTX-A injections have been used safely in the treatment of a number of clinical disorders (Maria et al, 2005), including neurogenic LUTD (Game et al, 2009). BTX-A has been subsequently applied to non-neurogenic LUTD, and there are a number of reports of BTX-A used to treat children with OAB and dysfunctional voiding (Steinhardt et al, 1997; Hoebeke et al, 2006; Mokhless et al, 2006; Radojicic et al, 2006; Franco et al, 2007; Petronijevic et al, 2007; Vricella et al, 2014). BTX-A is directly injected into the detrusor muscle (in patients with OAB) or external urinary sphincter (in patients with dysfunctional voiding) under cystoscopic guidance. One of the main drawbacks of this therapeutic modality is the need for re-treatment given the reversible nature of this chemical denervation secondary to synaptic terminal resprouting within 6 months of injection. Fortunately, preliminary studies suggest that repeated BTX-A injections are safe in children and do not induce additional fibrosis in the bladder wall (Pascali et al, 2011).

Neuromodulation

During the last two decades electrical nerve stimulation, also known as neuromodulation, has been applied to the treatment of non-neurogenic LUTD in children (Table 143-1). Several of the reported changes after treatment with neuromodulation include significantly increased bladder capacity, decreased severity of urgency, improved continence, and decreased UTIs (Bower et al, 2001; Hoebeke et al, 2001b; Roth et al, 2008). A significant improvement in urodynamic parameters of bladder compliance, number of involuntary contractions, and bladder volume at first detrusor contraction also have been noted (De Gennaro et al, 2004).

In neuromodulation, electrical stimuli are exerted in a noninvasive manner to alter the existent neural transmission pattern and modulate detrusor activity. The putative mechanism involves acting centrally by rebalancing excitatory and inhibitory information and returning the neural drive toward a more neutral status. A number of modalities have been studied in children, including sacral neuromodulation, pudendal nerve stimulation, and tibial nerve stimulation. Although preliminary results have been promising, electrical nerve stimulation's role in children with non-neurologic LUTD nevertheless remains controversial because of the lack of controlled trials and largely obscure mechanism of action.

With transcutaneous electrical nerve stimulation (TENS) superficial electrodes are placed on each side of the S3 and S2 spinal cord

Kramer and colleagues (2005) conducted the first randomized, placebo-controlled study of selective α -blocker therapy in children with dysfunctional voiding. Thirty-eight children were randomized to either placebo or 0.5 mg of doxazosin. Unlike in previous studies, they found no significant difference in the PVR and uroflow measurements between the treatment groups. There was a trend toward a significant improvement in urinary incontinence (4 vs. 14 incontinent episodes per week from a median baseline of 18 weekly episodes) and the DVSS parental survey in the α -blocker group compared to the placebo group. There was a significant difference in parental satisfaction, with a higher parental satisfaction in the children treated with α -blockade.

Vanderbrink and colleagues (2009) reported an observational study of 23 children with bladder neck dysfunction who were treated for an average of 10 months with tamsulosin. The number of incontinent episodes decreased from over 5.5 to less than 1 episode on average per day. In addition, increases in Qavg and Qmax and a reduction in PVR urine and abnormal uroflow patterns were observed during therapy. The safety profile for α -blockade in this pediatric population also was assessed, and the results were consistent with those in other reports using selective α -blockers in children. Although orthostatic hypotension was not formally evaluated, the authors did not find any significant alterations of blood pressure measurements and there were no reports of any symptomatology suggestive of hypotension.

TABLE 143-1 Studies Evaluating Neuromodulation in Treatment of Children with Lower Urinary Tract Dysfunction

REFERENCE	ES TYPE	LUTD	NO. PTS	TREATMENT SCHEME	FREQUENCY/AMPLITUDE	TREATMENT PERIOD	FOLLOW-UP (mo)	OUTCOME (%)
Hoebeke et al, 2001b	TENS	OAB	41	S3: 2 hr/day	2 Hz/not stated	6 mo	12	56 cured, 20 improved

BBD, bowel-bladder dysfunction; DV, dysfunctional voiding; ES, electrical stimulation; LUTD, lower urinary tract dysfunction; OAB, overactive bladder; PTNS, percutaneous tibial nerve stimulation; SNM, sacral nerve modulation; TENS, transcutaneous electrical nerve stimulation; UI, urinary incontinence; UR, urinary retention.

segments. In general, therapy consists of 20-minute sessions three times per week. Percutaneous tibial nerve stimulation (PTNS) is performed with a 34-gauge stainless steel needle inserted approximately 5 cm cephalad to the medial malleolus and a grounding pad placed just posterior to the medial malleolus. Proper needle placement in children is confirmed by observing ipsilateral plantar and/or toe flexion or fanning. Although the purported mechanism of action differs somewhat, neuromodulation by PTNS is based on the traditional Chinese practice using the Sanyinjiao acupuncture point, which overlies the posterior tibial nerve (van Balken et al, 2004). The posterior tibial nerve is a mixed sensory and motor nerve originating from the L4 to S3 spinal roots that also contributes to sensory and motor control of the bladder, urinary sphincter, and pelvic floor musculature. Therapy has been invariably applied once weekly, usually for 30-minute outpatient treatment sessions.

Since its initial description, a significant number of reports have been generated on sacral nerve root stimulation via implantable electrodes. In the last decade sacral nerve modulation (SNM) has gained widespread recognition in adults and was approved by the FDA for use in urology for urinary urgency/frequency, urge incontinence, pelvic floor dysfunction, and nonobstructive urinary retention. Despite off-label use, a number of groups have reported on their experience with SNM in children with non-neurogenic LUTD (Tanagho, 1992; Humphreys et al, 2006; Roth et al, 2008; McGee et al, 2009; Stephany et al, 2013).

Before sacral implantation can be performed, percutaneous transforaminal access to the S3 spinal nerve must be achieved. Once the correct responses are obtained, the quadripolar tined lead of the neurostimulator device can be implanted. This lead can then be connected to an external neurostimulator device via a tunneled subcutaneous extender for programming and trial assessments. If this is successful, the patient undergoes a second procedure to implant the permanent neurostimulator device into a subadipose pocket in the upper gluteal region. Complications commonly cited with implantable SNM devices are device and/or wound infection, electrode migration, loss of effect, and lead fracture. Revision rates range between 7% and 18%, secondary to lead migration, faulty connection, and infection.

Special Conditions of Lower Urinary Tract Dysfunction and Their Treatment

Giggle Incontinence (Enuresis Risoria)

Enuresis risoria is an uncommon form of daytime incontinence classically seen in school-aged females. Typically, moderate-to-large amounts of urinary leakage are triggered by laughing alone. The accepted theory is that of a central nervous system (CNS) inactivation (i.e., cataplexy) in association with laughter resulting in urinary incontinence (Sher and Reinberg, 1996). It should be emphasized that the incontinence episodes are invariably significant and often the entire bladder volume is drained. Daytime urinary incontinence in conjunction with laughter is also seen in children with OAB and is more common than true giggle incontinence. It is a diagnosis of exclusion and is usually established on history and is supplemented by the absence of other voiding symptoms and normal investigations. Giggle incontinence has a significant adverse effect on the social life, and this is often why medical assistance is sought. Currently, available treatment strategies include biofeedback or methylphenidate (Berry et al, 2009; Richardson and Palmer, 2009).

Pollakiuria (Extraordinary Daytime Urinary Frequency)

This is a disorder characterized by a very high daytime frequency of micturition (sometimes as high as 50 times per day). A key aspect of this syndrome, which differentiates it from OAB and often can clinch the diagnosis, is that the symptoms are limited only to the daytime. It is seen in early childhood (4 to 6 years of age) in both genders and associated with a history of recent death or life-threatening event in the family. Usually, it runs a benign, self-

KEY POINTS: MANAGEMENT OF DAYTIME URINARY INCONTINENCE AND BLADDER DYSFUNCTION

- The management of a child or adolescent with LUTD is primarily directed at improving symptoms (e.g., urinary and/or fecal incontinence, recurrent UTIs) and protecting the upper urinary tract from permanent damage.
- In general, a stepwise approach is used with an algorithm that progresses from least to most invasive with conservative measures (e.g., treatment of constipation, behavioral modification) exhausted before initiating medications, physical therapy, biofeedback, neuromodulation, or surgical intervention.
- In one large study, relief of constipation alone resulted in the disappearance of daytime urinary incontinence in 89% and enuresis in 63% of patients studied (Loening-Baucke, 1997).
- Anticholinergics are the current gold standard in the treatment of patients with symptoms referable to OAB. These agents act by reducing the frequency and intensity of uninhibited detrusor contractions during the filling phase of the bladder, resulting in an increase in the functional bladder capacity and compliance. The main side effects include constipation, dry mouth, blurred vision, reduced sweating, flushing, and altered behavior and cognition.
- α -Adrenergic blockade results in smooth muscle relaxation and decreased bladder outlet resistance to facilitate bladder emptying.
- In neuromodulation, electrical stimuli are exerted in a non-invasive manner to alter the existent neural transmission pattern and modulate detrusor activity. The putative mechanism involves acting centrally by rebalancing excitatory and inhibitory information and returning the neural drive toward a more neutral status. A number of modalities have been studied in children, including SNM, pudendal nerve stimulation, and tibial nerve stimulation.

limited course over a period of approximately 6 months (Bergmann et al, 2009). No specific treatment, apart from reassurance, is necessary. Children presenting with frequency, however, merit clinical investigation to exclude other pathologic causes.

Underactive Bladder

As the name suggests, underactive bladder describes a child who is required to raise intra-abdominal pressure to initiate, maintain, and complete voiding. Once a functional or anatomic cause for BOO has been ruled out, there are two main approaches to this entity. The first is with timed voiding and double voiding to more efficiently empty the bladder and lower the ultimate PVR volume of urine. If this treatment strategy fails to achieve the desired effect, we often recommend CIC with frequency dependent on symptom severity. Obviously, this requires appropriate counseling and thoughtful guidance of both patient and caregiver, especially in the child who is neurologically intact.

Vaginal Reflux (Vaginal Entrapment and Vaginal Voiding)

Vaginal reflux is characterized by incontinence after normal voiding in the absence of other LUTS. It is commonly seen in prepubertal girls, and the typical history is that of wetting of undergarments approximately 10 to 15 minutes after a normal void. It often can be associated with labial adhesions as a result of chronic irritation and inflammation from skin exposure to relatively caustic urine. Reassurance and postural modification to ensure complete vaginal emptying is the only treatment required.

ENURESIS

Over the last several decades, much has changed in our understanding of enuresis. Previous notions of voluntary control have been replaced by an appreciation of genetic and pathophysiologic mechanisms. What is known with certainty is that enuresis is a common medical condition in children (Shreeram et al, 2009). It affects millions of children throughout the world and is associated with significant negative impacts on self-esteem and health-related quality of life (Wolfe-Christensen et al, 2013).

Terminology and Background

The term *enuresis* is synonymous with *nocturnal enuresis* and is defined as discrete episodes of urinary incontinence during sleep in children over 5 years of age in the absence of congenital or acquired neurologic disorders. The term *diurnal enuresis* has been eliminated completely. The child who wets during the day and night can be said to have daytime urinary incontinence and enuresis or non-monosymptomatic enuresis.

Enuresis is categorized as monosymptomatic (MSE) or non-monosymptomatic (NMSE). MSE is defined as enuresis in children without any other LUTS and without a history of bladder dysfunction. MSE is further subdivided into *primary* and *secondary* forms. Children who have *never* achieved a satisfactory period of nighttime dryness (~80% of enuretic children fit this definition) have primary MSE (Friman and Warzack, 1990). Children who develop enuresis after a dry period of at least 6 months are said to have secondary enuresis (von Gontard and Nevés, 2006). Secondary enuresis often is ascribed to an unusually stressful event (e.g., parental divorce, birth of a sibling, sexual abuse) or an organic (e.g., UTI, diabetes, obstructive sleep apnea, neurogenic bladder) or psychological cause (e.g., ADHD or conduct disorder) at a time of vulnerability in a child's life. These children are more likely to have NMSE (see next) and respond less well to treatment. The exact cause of secondary MSE, however, remains largely unknown. The clinical presentations of children with primary and secondary MSE are otherwise similar, which suggests a common pathogenesis (Robson et al, 2005). Moreover, large family studies have demonstrated that secondary MSE is usually no different etiologically from primary MSE, with undue emphasis on their difference being unwarranted (Schaumburg et al, 2008).

Enuresis with any daytime LUTS is defined as NMSE (Franco et al, 2013). Daytime LUTS suggesting NMSE include daytime incontinence (not obligatory), frequency, genital or LUT pain, and holding maneuvers (i.e., strategies to postpone voiding). A careful history is often required to elicit these symptoms, which usually indicate either OAB (i.e., a storage issue) such as urgency or dysfunctional voiding (i.e., emptying problems) such as hesitancy, straining, weak stream, intermittency or a feeling of incomplete emptying.

The pathogenesis, evaluation, and treatment of MSE and NMSE overlap considerably (Nevés et al, 2010). Approximately 15% to 30% of enuretic children experience daytime LUTS; however, these reported numbers are likely grossly underestimated (Järvelin et al, 1988; Gumus et al, 1999). In fact, most experts in the field would estimate the proportion of children with enuresis that are truly monosymptomatic to represent fewer than half of all bedwetting children (Franco et al, 2013).

Our initial approach to NMSE is nearly identical to our approach for children with LUTD. Obviously one begins with a thorough history and physical examination, along with the appropriate laboratory and imaging studies. In terms of NMSE therapy, we also begin by identification and treatment of constipation. As we have previously seen, effective treatment of bowel problems can lead to the spontaneous remission of daytime incontinence (Loening-Baucke, 1997). We also will treat the underlying LUTD symptoms first, because effective treatment of OAB (or dysfunctional voiding) can lead to cessation of the enuresis entirely (Franco et al, 2013). If comorbid behavioral disorders are present, these should be addressed by an appropriate provider. If enuresis persists after the

Figure 143-9. Prevalence rate of enuresis from childhood through young adulthood. (From Austin PF, Nevés T. Evaluation and management of enuresis. AUA Update Series, Vol. XXI, 2012.)

previously mentioned interventions, standard treatment for MSE can follow. The remaining section of this chapter will focus specifically on MSE and its epidemiology, cause, evaluation, and treatment strategies.

Epidemiology and Natural History

Enuresis is a common problem, with an estimated 7 million children in the United States alone with this condition. According to a recent large longitudinal study in the United Kingdom, at least 20% of children in the first grade occasionally wet the bed and 4% wet the bed two or more times per week (Butler and Heron, 2008). Prevalence varies with age, suggesting an immaturity of the LUT and nervous system (Fig. 143-9). In a study of almost 11,000 children in the United States, the prevalence of enuresis in boys at 7 and 10 years of age was 9% and 7%, respectively, and in girls at those ages, 6% and 3%, respectively (Byrd et al, 1996). It is currently generally accepted that in the West approximately 15% of children will have some degree of nighttime wetting at 5 years of age, with a spontaneous resolution rate of approximately 15% per year (Forsythe and Redmond, 1974). Consequently, at 15 years of age only 1% to 2% of teenagers will still wet the bed (Klackenberg, 1981). It has also been shown that the longer the enuresis persists, the lower the probability is that it will resolve spontaneously (Forsythe and Redmond, 1974; Bakker et al, 2002).

Enuresis seems to be more common in boys than in girls, with most reports revealing a 2:1 ratio. Although this finding has been disputed by other groups, it is well accepted that by adolescence the prevalence in both males and females reaches equipoise (Yeung et al, 2004b).

Enuresis is also known to be common in children with comorbid behavioral issues such as ADHD, oppositional defiant disorder, conduct disorder, anxiety, and depression (Baeyens et al, 2004; von Gontard et al, 2011). It is estimated that 20% to 30% of children with enuresis have comorbid clinical behavioral disorders that fulfill the criteria for the DSM-V psychiatric disorders and may subsequently have a negative impact on compliance and ultimate outcome if left untreated (von Gontard et al, 2011).

Genetics

Enuresis has a complex and multifactorial pathophysiology with a strong genetic underpinning (von Gontard et al, 1998a; Schaumburg et al, 2008). When one or both parents have a history of prolonged nighttime wetting, approximately 43% and 77%, respectively, of the offspring are affected (Bakwin, 1973). When neither parent has a history of nocturnal enuresis, only 15% of offspring are affected (Bakwin, 1973). Moreover, the concordance among

monozygotic twins is almost twice that among dizygotic twins (68% vs. 36%) (Bakwin, 1971). Linkage of enuresis to markers on chromosomes 12, 13, and 22 has been reported, with autosomal dominant inheritance and high penetrance suggested; however, a major gene locus has yet to be identified (Eiberg et al, 1995, Eiberg 1998; Arnell et al, 1997). Family and twin studies suggest locus heterogeneity and poor phenotype-genotype correlation (von Gontard et al, 2011b). The identification of these genes certainly lifts the burden of guilt from children who have enuresis and helps to dispel the theory that enuresis is behavioral in origin and completely under their control.

Pathophysiology

It is generally accepted that enuresis stems from a maturational delay in the ultimate development of bladder control (Järvelin, 1989; Light, 1998). This contention is rooted in the fact that most children eventually attain nocturnal dryness regardless of what intervention is used and even if enuresis is left untreated. The hypothesis that there is a difference in the CNS maturation in children with primary enuresis compared with controls is supported by neurophysiologic data (Isacan et al, 2002). Many children who have enuresis are noted to have progressive maturation of bladder stability in conjunction with electroencephalography (EEG) findings that suggest increased CNS recognition of bladder fullness and the ultimate ability to suppress the onset of bladder contraction (Watanabe and Azuma, 1989). This would further lend credence to the premise that delayed maturation of the bladder control plays a role in MSE.

Put very simply, the three organ systems implicated in the pathogenesis of enuresis include the bladder (i.e., a reduced nocturnal bladder capacity) (Yeung et al, 2004a), the kidney (i.e., nocturnal polyuria) (Nørgaard et al, 1989a; Vande Walle et al, 2007), and the brain (i.e., a disorder affecting arousal from sleep) (Watanabe and Azuma, 1989; Isacan et al, 2002). Enuresis is logically thought to result from a disruption or maturational lag in one or more of these critical domains (Fig. 143-10).

Bladder Overactivity and Reduced Nocturnal Bladder Capacity

There seems to be a subset of children with primary MSE who have nocturnal bladder overactivity regardless of amount of urine production (Yeung et al, 1999). Yeung and associates found that nearly half of treatment failures with standard therapy (i.e., desmopressin or moisture alarm) had normal daytime bladder function but marked detrusor overactivity during sleep that resulted in enuresis. Almost none of these children had nocturnal polyuria.

When urodynamic studies are performed during sleep, the only difference between children with and without MSE is the increased rate of bladder contractions that occur in association with the enuretic episode (Nørgaard et al, 1989b). In addition, urodynamic

studies during sleep demonstrate a relationship between nocturnal enuresis and pelvic floor activity. When pelvic floor activity increased in association with detrusor contractions, wetting was usually avoided, and patients often would awaken subsequently to void. In contrast, when pelvic floor activity did not increase, the detrusor contraction usually was associated with a wetting episode (Nørgaard et al, 1989b).

Please see the Expert Consult website for further details.

Nocturnal Polyuria

Increased nighttime urine output appears to play an important role in nocturnal enuresis (Nevéus et al, 2010). In children and adolescents without enuresis, the diurnal pattern of urine production results in a relative reduction in nocturnal diuresis to approximately 50% of daytime levels (Rittig et al, 1995, 2010). The prevailing mechanism for how this occurs is thought to result from a nocturnal circadian peak of antidiuretic hormone (ADH) release from the posterior pituitary gland that regulates free water excretion. Other purported mechanisms for increased nocturnal urine production may include increased fluid intake before bedtime (Robson, 2001), a blunted response to ADH, increased evening dietary solute load with high nocturnal urine osmolality (Dehoorne et al, 2006), abnormal renal sodium handling (related to release of angiotensin II, aldosterone, and natriuretic peptide), abnormal circadian rhythm of glomerular filtration rate (De Guchteneere et al, 2007), abnormal sodium and calcium excretion (Raes et al, 2006), and obstructive sleep apnea/hypoventilation (Su et al, 2011).

Regardless of the mechanism, urine production that normally decreases at night secondary to these circadian systems fails to do so and will subsequently result in nocturnal polyuria, which can exceed the functional capacity of the bladder and result in an enuretic episode. Proof of this concept was demonstrated by Rasmussen and colleagues (1996), who were able to actually induce enuresis in normal healthy children by increasing nocturnal urine output. Despite this seemingly simple causal relationship, however, it is clear that nocturnal polyuria and ADH responsiveness are highly complex phenomena, because not all children with enuresis have nocturnal polyuria and, in those who do, nocturnal ADH may be normal (Steffens et al, 1993). In fact, it has been observed that the urine osmolality of children with and without MSE is similar and that early morning osmolality tends to increase with age (Kawauchi et al, 1996). This suggests that the ADH secretion response may be a maturational one and lend further support to the maturation hypothesis.

Arousal and Sleep

Regardless of whether the child has detrusor overactivity and/or nocturnal polyuria, neither observation explains why a child with enuresis is unable to awaken from sleep to void before a wetting episode. Given that both bladder distention and detrusor contractions are robust arousal stimuli (Koyama et al, 1998), it is curious that an enuretic child will not wake up during the night to the sensation of a full or contracting bladder. Parents invariably describe their children with enuresis as excessively deep sleepers (Wille, 1994; Nevéus et al, 1999a). This situation is often experienced by family members of patients exposed to alarm therapy as parents awaken from sleep while their enuretic child will sleep through the alarm. Nevéus and colleagues (1999a) obtained questionnaire data from 1413 schoolchildren between the ages of 6 and 10 years and noted that enuresis was associated with subjectively high threshold arousal and significant confusion on awakening from sleep. Wolfish and coworkers (1997) performed a laboratory study of 33 boys aged 7 to 12 years (15 with enuresis and 18 age-matched controls) and found that attempts at arousal were more often successful in control subjects than in boys with enuresis (40% vs. 9%, respectively).

A subjectively deep sleep, however, is not the same as an objectively deep sleep, as measured by EEG. Freitag and associates (2006) studied brainstem evoked potentials in 37 children with MSE and compared these children to 40 age-matched controls. They found

Figure 143-10. Organ system involvement in pathogenesis of enuresis.

Children with enuresis (even those without daytime symptoms) have been noted to have a smaller bladder capacity than age-matched children controls (Starfield, 1967). The reduced bladder capacity appears to be functional rather than anatomic. This was illustrated by a study in which bladder capacity was measured in the awake state as well as under general anesthesia in children with enuresis and compared with functional bladder capacity among controls (Troup et al, 1971). Compared with control children, the average volume of urine voided by enuretic children in the awake state was reduced. However, when volumes were measured during general anesthesia, enuretic children had similar mean bladder volumes to awake controls. In a somewhat contradictory study, Kawauchi and colleagues (2003) found that the maximal endurable bladder capacity during the daytime was similar between children with enuresis and controls. However, among children with enuresis, the maximal voided volume during the night (measured using a diaper and enuresis alarm) was significantly smaller than the maximal daytime bladder capacity. They concluded that inability to hold urine during sleep may be an important factor in MSE. A number of trials have noted functional bladder capacity to be a strong predictor of response to desmopressin in MSE (Rushton et al, 1996; Eller et al, 1998). As a result, a refractory response to desmopressin may suggest either unrecognized nocturnal OAB or that the decreased nocturnal urine production elicited by desmopressin continues to overwhelm a functionally undersized bladder. Whether this situation is a result of reduced nocturnal functional bladder capacity or nocturnal detrusor overactivity, however, may not be critical because the treatment strategy employed would largely be the same (i.e., anticholinergic medications).

that interpeak latencies of the brainstem evoked potentials were increased in children with MSE, suggesting a maturational defect of the brainstem to account for this finding. Other sleep studies, however, show that sleep patterns among children with and without enuresis are similar (Ritvo et al, 1969; Bader et al, 2002). These studies indicate that enuretic episodes may occur at random throughout the night, but primarily during nonrapid eye movement (non-REM) sleep (Nevéus et al, 1999b) and when the bladder is at a volume equivalent to the maximal daytime functional capacity (Mikkelsen et al, 1980; Nørgaard et al, 1989b). A study of 35 children with therapy-resistant MSE in Hong Kong demonstrated that although appearing to be heavy sleepers, these children had, in fact, more overall light sleep (stage I/II non-REM) with sleep fragmentation, rather than deep sleep (stage III/IV non-REM). The cerebral cortex received afferent input of sleep OAB with frequent cortical arousals that failed to wake the children, which was presumed to be a paradoxical elevation in the conscious awakening threshold. OAB-associated cortical arousals may cause a shift from deep to light sleep but not to complete awakening, perhaps because of long-term overstimulation of the sleep arousal center by signals from the bladder. In summary, these studies suggest that children who wet the bed sleep normally (i.e., the distribution and proportion of the various stages of sleep are within normal limits) but are unable to awaken in response to nocturnal detrusor contractions or bladder fullness.

Evaluation

The basic evaluation of the child with MSE includes **history, physical examination, and urinalysis. The history, including a voiding diary, is the mainstay of the evaluation** (Robson, 2009; Nevéus et al, 2010). As previously discussed, the voiding diary is an objective means of documenting the voiding pattern (see section on *Bladder and Bowel Diaries*). This is especially useful when the history is unclear. A voiding diary kept by the parents should help assess the times at which a child voids; the relationship between voiding and common events such as meals, breaks at school, and play activities; the occurrence of urgency or incontinence; and voided volume. **The principal objective of the evaluation is to rule out BBD or enuresis as a manifestation of an underlying medical disease (e.g., posterior urethral valves, spinal dysraphism, diabetes mellitus) and to identify that the enuresis is truly monosymptomatic.** If BBD is present, it should be treated as described previously before initiating therapy for MSE (Franco et al, 2013).

Once MSE is confirmed, it is often helpful to characterize the enuresis further, such as frequency and volume. Distinguishing between primary and secondary MSE should be attempted, mainly for prognostic purposes because treatment is generally the same. One important point to ask about is the presence of nocturia; this would suggest that the child is not extremely difficult to arouse from sleep. The social history is also particularly germane because somatic and psychological comorbid conditions are more common in children who were previously dry than in those with primary MSE (Robson et al, 2005). A family history of enuresis is often helpful in establishing a genetic pattern. Interventions the family has already tried also should be determined.

The physical examination should be focused and is similar in scope to that described in the prior section on LUTD. Briefly, examination should include palpation of the abdomen to screen for constipation, examination of the lower spine for cutaneous stigmata of spinal dysraphism, examination of the genitalia to screen for meatal stenosis, introital erythema or damp/wet underwear, assessment of the sacral reflex arc, and evaluation of the motor strength, tone, reflexes, and sensation in the legs for evidence of a neurogenic bladder.

In terms of laboratory testing, a simple urinalysis should be performed to detect any possible glucosuria, proteinuria, hematuria, pyuria, and/or bacteriuria. Neither radiologic imaging nor urodynamics has a role in the evaluation of MSE. If based on history and physical examination the patient is suspected to have NMSE, we would recommend evaluation following the previously

described protocol for children with LUTD (i.e., pelvic ultrasound and uroflowmetry).

Treatment

Conventional therapies for enuresis include behavioral modification, the enuresis “moisture” alarm, and pharmacologic therapy (e.g., desmopressin, anticholinergics, imipramine). The evidence for the efficacy of much of the care that we provide to children with enuresis is weak (Nevéus et al, 2010). Given the self-limiting nature of enuresis, one treatment option is to observe and allow the natural history to follow its predetermined course. However, enuresis that occurs as infrequently as once per month is associated with reduced self-esteem and treatment has been reported to improve self-worth, regardless of the type or the success of therapy (Hägglöf et al, 1998; Longstaffe et al, 2000).

The decision about when to start treatment generally should be guided by the degree of concern and motivation on the part of the child rather than the parents. For the child, nocturnal enuresis usually becomes significant when it interferes with his or her ability to socialize with peers (e.g., sleepovers, summer camps) (Jalkut et al, 2001). **It is important to determine whether the child is mature enough to assume responsibility for treatment.** Treatment probably should be delayed if it seems that the parents are more interested in treatment than the child and the child is unwilling or unable to assume some responsibility for the treatment program. The child must be highly motivated to participate in a treatment program that may take months to achieve successful results. Although general advice should be given to all bedwetting children, active treatment should usually not be started before 6 years of age (Nevéus et al, 2010). However, age should not be the only criterion for initiation of active treatment.

Behavioral Therapy

Data from randomized trials on the efficacy of behavioral therapy are lacking (Pennesi et al, 2004; Caldwell et al, 2013), but clinical experience (i.e., level 4 evidence) suggests that this approach is beneficial (Nevéus et al, 2010). Likewise, although the influence of the clinician's behavior has not been formally studied, clinical experience suggests that the ability to establish a rapport with the child and to engender and sustain motivation is important for successful behavioral therapy. **The fundamental goal of behavioral therapy is much like the treatment of daytime urinary incontinence and centers around the practice of good bladder and bowel habits.**

Children should attempt to void regularly during the day and just before going to bed for a total of six to seven times daily. High-sugar and caffeine-based drinks should be avoided, particularly in the evening hours. Daily fluid intake should be concentrated in the morning and early afternoon, and both fluid and solute intake should be minimized during the evening. Isolated nighttime fluid restriction, without compensatory increase in daytime fluid consumption, may prevent the child from meeting his or her daily fluid requirement and is usually unsuccessful.

In practice, compliance improves when parents and children understand normal bladder function and the pathogenesis of enuresis. **Children should be reassured that enuresis is not their fault, and children should not be punished for bedwetting, because this practice is often counterproductive** (van Londen et al, 1993). An individualized program with a series of realistic goals between appointments and monthly follow-up to sustain motivation improves the outcome (Glazener and Evans, 2004). A personalized calendar for recording daytime incontinence and enuresis episodes and the frequency and timing of bowel movements aids the family and child to follow their progress.

When initiating active treatment for primary MSE, there is level 1 evidence to support the use of the enuresis alarm (Glazener et al, 2005), **desmopressin** (Glazener and Evans, 2009), **anticholinergics** (Austin et al, 2008), and **tricyclic antidepressants (e.g., imipramine)** (Glazener and Evans, 2000), either alone or in combination. Generally, in addition to behavioral therapy, the two

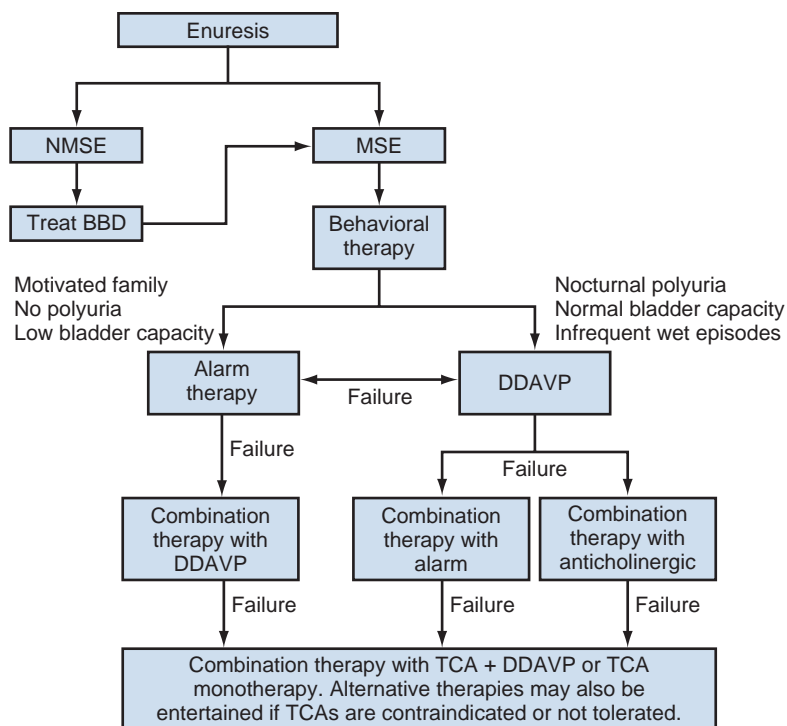

Figure 143-11. Algorithm of the evaluation and treatment of a pediatric patient with enuresis. BBD, bowel-bladder dysfunction; DDAVP, 1-deamino-8-D-arginine vasopressin (desmopressin); MSE, monosymptomatic enuresis; NMSE, nonmonosymptomatic enuresis; TCA, tricyclic antidepressant.

contemporary first-line therapies for MSE include the enuresis alarm and desmopressin. They are both valid treatment options, but patient, caregiver, and disease-related parameters exist that may aid in offering prognostic information in terms of which therapeutic modality should be first entertained (Fig. 143-11). The enuresis alarm seems best fit for motivated families and for children without polyuria but with low voided volume (Nevéus et al, 2010). Desmopressin seems best suited for children with nocturnal polyuria and normal bladder reservoir function (Hunsballe et al, 1998), those with infrequent wet episodes, and for families in whom alarm treatment has failed or who have refused alarm treatment (Nevéus et al, 2010). Children in whom one first-line treatment has failed should be offered the other, and for those in whom both have failed, second- and third-line treatments can be tried, either alone or in combination (e.g., desmopressin plus oxybutynin).

Enuresis Alarm

Alarm training has been shown to be the most effective long-term therapeutic modality in the treatment of MSE (Glazener et al, 2005). Alarms have been used since the 1930s and represent classic pavlovian conditioning techniques, but exactly how the alarm works remains somewhat of a mystery because, strictly speaking, classical conditioning mechanisms should not be functional during sleep. Proposed mechanisms include suppression of bladder emptying during sleep, increasing nocturnal bladder volume (Hansen and Jørgensen, 1997), and waking to void by signaling when they urinate. Interestingly, most children who become dry with the use of the enuresis alarm actually sleep through the night and do not necessarily wake to void. The response is more gradual and sustained than for desmopressin, with approximately two thirds of children becoming dry during active treatment and nearly half remaining dry after treatment completion (Glazener et al, 2005). Enuresis alarms are activated when a sensor, placed in the undergarments or on a bed pad, detects moisture, with both types demon-

strated to be equally effective (Butler and Robinson, 2002). The arousal device is usually an auditory alarm and/or a vibrating belt.

The family should be instructed that the child is in charge of the alarm. After the alarm goes off, only the child should turn off the alarm, get up, and finish voiding in the toilet. We often remind parents that at the initiation of therapy, the child may fail to awaken and that parents should wake the child when the alarm sounds. The child being fully awake and cognizant of what is happening is critical to the success of alarm therapy. The child should then return to the bedroom, change the bedding and underwear, replace the sensor, and reset the alarm before returning to sleep. A diary should be kept of wet and dry nights, with positive reinforcement given for dry nights as well as successful completion of the sequence of events. Approximately 30% of patients discontinue enuresis alarms for various reasons, including skin irritation, disturbance of other family members, and/or failure to wake the child (Schmitt, 1997). Adverse effects of alarms include alarm failure, false alarms, disruption of the lives of other family members, and lack of adherence because of difficulty using the alarm (Glazener et al, 2005).

Alarm treatment should be continued until the child has had a minimum of 14 consecutive dry nights (Nevéus et al, 2010). Children who do not continue to improve after 6 weeks of alarm training are unlikely to become completely dry with this technique (Taylor and Turner, 1975), and alternative interventions may be warranted. Therapy with the alarm can be reinitiated for relapse (more than two wet nights in 2 weeks). Children who relapse after discontinuation of the alarm usually can achieve a rapid secondary response because of preconditioning as a result of the first treatment program (Tuncel et al, 2008). During this refractory treatment period, the chance of long-term cure can be increased by a technique called *overlearning* (Morgan, 1978). In overlearning, additional fluids are given at bedtime while alarm training is continued after dryness has been achieved (Young and Morgan, 1972). In alarm training without overlearning, the child trains to inhibit urination without necessarily learning to wake to void. A systematic review indicated that overlearning trains the child to wake in

response to the sense of a full bladder and reduces relapse when alarm treatment is stopped (Glazener et al, 2005).

Pharmacotherapy

Desmopressin

Desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]) is a synthetic analogue of ADH released by the posterior pituitary gland that reduces urine production by increasing water reabsorption by the collecting tubules. DDAVP has been used to treat enuresis for the past 40 years. Desmopressin is fairly easy to administer and its clinical effects appear immediately, with a serum half-life of approximately 2 to 3 hours when taken in oral form (the duration of pharmacodynamic action approximates the average duration of sleep for a child in the age range for elementary school). It is available in the United States in oral (crushable) tablets and in sublingual and intranasal spray formulations. The main safety issue is the risk for water intoxication with resultant hyponatremic seizures should the drug be taken with excessive fluids. This risk seems to be somewhat higher with the intranasal form, which has a prolonged half-life, and thus use of the spray is discouraged (Robson et al, 2007). Treatment should be interrupted during episodes of fluid and/or electrolyte imbalance (e.g., fevers, vomiting or diarrhea, vigorous exercise, or other conditions associated with increased water consumption).

The usual starting dose is 0.2 mg orally 1 hour before bedtime, and the drug can be titrated up incrementally by 0.2 mg to a maximum dose of 0.6 mg at bedtime. Children are instructed to void directly before going to bed. Fluid intake is reduced to a maximum of one 8-oz glass at the time of ingestion, with absolutely no more fluids until morning, decreasing the risk for significant hyponatremia to virtually zero (Glazener and Evans, 2009).

Desmopressin is most efficient in children with nocturnal polyuria (defined by the ICCS as nocturnal urine production >130% of expected bladder capacity for age) and normal bladder reservoir function (maximum voided volume >70% of expected bladder capacity for age) (Rushton et al, 1996; Hunsballe et al, 1998; Austin et al, 2014). There is a wide range of efficacy among studies, most likely because of heterogeneous patient populations (MSE vs. NMSE), differences in concomitant behavioral therapy recommendations, and differences in the dosage or formulation of DDAVP, without taking into account nocturnal urine volume. Overall, approximately 30% of patients achieve total dryness and another 40% exhibit a significant decrease in nighttime wetting (Nevéus et al, 2010). However, the relapse rate after discontinuation is high (60% to 70%) (Wille, 1986). In a systematic review of 47 randomized trials (3448 children), researchers noted that compared with placebo, children treated with desmopressin were more likely to become dry and had a reduction in bedwetting by 1.34 nights per week (Glazener and Evans, 2009). In contrast to the enuresis alarm, however, treatment effects were not sustained after discontinuation of therapy, with a relapse rate of 65% versus 46% with DDAVP versus the alarm, respectively (Glazener and Evans, 2009).

The response to desmopressin should be assessed within 2 weeks (Schmitt, 1997). Treatment should be continued if there is a positive response (e.g., smaller wet patches, fewer wetting episodes). If enuresis improves or remits with desmopressin, the family and child can determine whether to use it every night or just for special occasions (e.g., sleepovers, summer camp). When DDAVP is administered daily, we generally give patients regular scheduled drug holidays of approximately 1 week every 3 to 6 months to assess whether the medication is still needed.

Tricyclic Antidepressants

Tricyclic antidepressants (TCAs) have been demonstrated to decrease the amount of time spent in rapid eye movement (REM) sleep, stimulate ADH secretion, and relax the detrusor muscle via weak anticholinergic properties. Its antienuretic effect has been theorized

to be less likely because of its action at the kidney or bladder level and more likely a result of noradrenergic stimulation at the brainstem, specifically the locus coeruleus (Gepertz and Nevéus, 2004). Given the efficacy and safety of enuresis alarms and DDAVP, TCAs (e.g., imipramine, amitriptyline, and desipramine) are considered a third-line treatment for therapy-resistant MSE (Nevéus et al, 2010).

Level 1 evidence demonstrates that compared to placebo, TCAs are more effective at reducing the number of wet nights and at achieving 14 consecutive dry nights (i.e., cure) but essentially become ineffective once treatment is discontinued.

Please see the Expert Consult website for further details.

Although other TCAs are effective, imipramine is used most often in the treatment of enuresis. Imipramine is available in 10-, 25-, and 50-mg tablets. The initial dose is 10 to 25 mg 1 hour before bedtime; it may be increased by 25 mg if there is no response after 1 week (Schmitt, 1997). On average, the bedtime dose is 25 mg for children 5 to 8 years of age and 50 mg for older children. The dose should not exceed 50 mg in children between 6 and 12 years of age and 75 mg in children older than 12 years of age (Glazener and Evans, 2000).

The response to imipramine should be assessed after 1 month. If there is no improvement after 3 months, it should be discontinued as a gradual taper (as is done with other TCAs). As is the case with other pharmacotherapy for enuresis, we give patients a drug holiday every 3 to 6 months, gradually tapering the dose over a 2-week period (Gepertz and Nevéus, 2004).

Adverse effects of TCA therapy are relatively uncommon. Approximately 5% of children treated with TCAs develop neurologic symptoms, including nervousness, personality change, and disordered sleep. TCAs (as with other antidepressants) are required by the FDA to carry a black box warning regarding the possibility of increased suicidality, particularly in individuals with preexisting depressive symptoms. The most serious adverse effects of TCAs involve the cardiovascular system: cardiac conduction disturbances and myocardial depression, particularly in cases of overdose (Swanson et al, 1997). Before initiation of therapy with a TCA, a thorough cardiac history (e.g., palpitations, syncope) and family cardiac history (e.g., arrhythmias, sudden cardiac death) should be obtained with a baseline electrocardiogram to rule out a prolonged QT interval if history or physical examination raises suspicion.

Anticholinergics

Monotherapy with anticholinergic drugs, such as oxybutynin or tolterodine, has been demonstrated not to be effective as a first line of treatment for MSE (Lovering et al, 1988; Persson-Jünemann et al, 1993). Although evidence of efficacy from randomized trials is lacking, uncontrolled studies do show improvement in some children with NMSE, presumably because many of these children have a reduced functional bladder capacity (Caione et al, 1997; Nevéus, 2001). There is also some evidence that nocturnal detrusor overactivity (especially without nocturnal polyuria) plays a role in the pathogenesis of enuresis and therefore makes anticholinergics an attractive pharmacotherapeutic option (Nevéus, 2001).

Where anticholinergics clearly do have a role is combination therapy in the treatment of children who are refractory to DDAVP monotherapy. In the first randomized, placebo controlled study of combination therapy with anticholinergics, Austin and colleagues (2008) studied 34 children with primary MSE who failed maximal-dose DDAVP monotherapy and assigned them, in a double-blind manner, to receive either extended-release tolterodine or placebo while all children continued to take DDAVP. Patients were reassessed after 1 month of therapy with a 1-week nocturnal record. They found a significant reduction in the mean number of wet nights in the combination therapy group compared to the placebo group. With a generalized estimating equation approach, there was a significant 66% reduction in the risk for a wet episode compared with the placebo group. Recently, Montaldo and associates (2012) reported their results in 206 children with MSE refractory to DDAVP monotherapy who were randomized to 5 mg of oxybutynin or placebo and followed for 1 month. As predictive factors, bladder

In a recent systematic review, treatment with TCAs was associated with a reduction of approximately one wet night per week compared to placebo ([Glazener and Evans, 2000](#)). Approximately 20% of children became dry during therapy versus 5% with placebo. The rate of relapse was 96% after discontinuation of therapy. In an observational study of children who were refractory to first-line therapy, researchers found that approximately one third of children became dry on monotherapy, one third became dry after adding DDAVP, and the remaining third were nonresponders ([Gepertz and Nevéus, 2004](#)).

volume and wall thickness index, nocturnal polyuria, and voiding latency were considered. Corroborating the original study by Austin and associates, the oxybutynin group showed a higher rate of full and partial responses than the placebo group. The responders to combined oxybutynin and desmopressin had a significantly lower bladder volume and wall thickness index than nonresponders.

Combination Therapy

The efficacy of the enuresis alarm plus desmopressin combination has been investigated in a number of studies (Sukhai et al, 1989; Bradbury, 1997; Leebeek-Groenewegen et al, 2001; Fai-Ngo et al, 2005).

Please see the Expert Consult website for further details.

A reduction in the number of wet nights is consistently observed when using combination therapy of desmopressin and the moisture alarm compared to monotherapy. Enuresis relapse, however, is noted in some patients with long-term follow-up.

Alternative Therapies

Other drugs, including indomethacin, ephedrine, atropine, furosemide, and diclofenac, have been tried in the treatment of enuresis. A recent systematic review of randomized trials of drugs other than TCAs and DDAVP found that although indomethacin, diclofenac, and diazepam were better than placebo in reducing the number of wet nights, none of the drugs was better than desmopressin (Deshpande et al, 2012). A second recent review of complementary approaches such as hypnosis, psychotherapy, and acupuncture found limited evidence from small trials with methodologic limitations to support the use of such modalities for the treatment of enuresis (Huang et al, 2011).

KEY POINTS: ENURESIS

- The majority of children who present with enuresis have the nonmonosymptomatic form.
- The spontaneous resolution rate of enuresis is approximately 15% annually, such that only approximately 1% of teenagers will continue to be afflicted.
- Enuresis stems from a maturational delay in the ultimate development of bladder control, with three organ systems implicated in its pathogenesis: the bladder, the kidney, and the brain.
- The basic evaluation of the child with MSE includes history (including a voiding diary), physical examination, and urinalysis. The principal objective of the evaluation is to rule out BBD or enuresis as a manifestation of an underlying medical disease (e.g., posterior urethral valves, spinal dysraphism, diabetes mellitus) and to identify that the enuresis is truly monosymptomatic.
- Conventional therapies for enuresis include behavioral modification, the enuresis moisture alarm, and pharmacologic therapy (e.g., desmopressin, anticholinergics, imipramine).

Sukhai and colleagues (1989) reported a crossover trial of 28 children with primary MSE who were blindly allocated at random to a combination of enuresis alarm plus 20 µg intranasal DDAVP or alarm plus placebo for 2 weeks. Patients received the other therapy after a 2-week treatment-free period. The combined treatment of desmopressin plus enuresis alarm resulted in significantly more dry nights per week during the 2 weeks of observation than placebo plus the alarm. Although there was a significant difference between groups, the treatment period of 2 weeks was most likely too short for alarm therapy to contribute significantly to the outcome variable.

Bradbury compared the efficacy of enuresis alarm monotherapy to alarm treatment in combination with 40 µg DDAVP nasal spray (Bradbury, 1997). At the end of the treatment period, children receiving combination therapy had more dry nights per week (mean: 6.1) than children using an alarm alone (mean: 4.8). In addition, more children achieved an initial success (4 weeks of dryness) after combination treatment (27 children [75%]) compared with alarm monotherapy (16 children [46%]). Interestingly, this improvement was most pronounced in children with severe wetting (>5 nights per week), family problems, or behavioral problems.

In a placebo-controlled study containing 93 patients with MSE, Leebeek-Groenewegen and colleagues (2001) compared 9 weeks of desmopressin plus alarm therapy with alarm monotherapy. They showed a significant decrease in the number of wet nights per week with combination therapy. After 6 months of follow-up, however, they reported that there was no significant difference between the two treatment groups regarding the efficacy and number of children who relapsed.

In a recent multicenter randomized controlled trial, Fai-Ngo et al (2005) compared the efficacy of the enuresis alarm, oral DDAVP, and combined treatment in children with primary MSE. They assigned 105 children equally among groups to receive treatment for 12 weeks, and patients were then followed for 12 weeks after treatment. They found that the mean number of wet nights per week was significantly lower in the combination group than in the other groups at the conclusion of therapy. Desmopressin produced an immediate effect but relapses were most common in the DDAVP monotherapy and combination therapy groups (60% and 40%, respectively). Alarms took several weeks to produce a benefit, but this was sustained on follow-up (20% relapse rate).

Daytime Urinary Incontinence and Bladder Dysfunction

Enuresis

CLINICAL SIGNIFICANCE

Functional disorders of the lower urinary tract (LUT) encompass abnormalities in the filling and/or emptying phases of the bladder and include a broad spectrum of clinical entities that vary in their cause and prognosis. These are functional disorders in that children do not have a readily identifiable neurologic or anatomic abnormality but rather the disorder is thought to originate from behavioral factors that affect toilet training and inhibit the development of normal urinary control. *LUT dysfunction (LUTD)*, *bladder and bowel dysfunction*, and the antiquated *dysfunctional elimination syndrome*, are terms that describe the common array of symptoms that include overactive bladder (OAB), voiding postponement, underactive bladder, dysfunctional voiding, primary bladder neck dysfunction, giggle incontinence, vaginal reflux, pollakiuria, and enuresis.

Evidence-based medicine lends support to the hypothesis that LUTD can predispose children to recurrent urinary tract infections (UTIs) and vesicoureteral reflux (VUR) with a potential for significant impact on subsequent LUT and renal function. Beyond these largely urologic sequelae, however, the impact of symptoms such as daytime incontinence are profound and can affect the behavioral, emotional, and social aspects of a child's daily life. Timely diagnosis and a coherent therapeutic approach are therefore paramount in the successful treatment of these physically and emotionally distressing disorders.

EPIDEMIOLOGY

LUTD is commonly encountered in daily practice, accounting for up to 40% of pediatric urology clinic visits annually (Feldman and Bauer, 2006). Cross-sectional studies confirm that functional LUT problems are prevalent, with 22% of school-age children reporting at least one LUT symptom. The most common urinary symptoms cited included holding maneuvers (19.1%) and urgency (13.7%) (Vaz et al, 2012).

United States

Daytime incontinence is estimated to affect up to 7 million children in the United States 6 years of age or older (Franco, 2012). OAB is the most commonly encountered LUT disorder in children and appears to have a peak incidence between 5 and 7 years of age, although its true prevalence is difficult to determine (Franco, 2007). To date, studies have focused primarily on daytime versus nighttime incontinence and have not attempted to differentiate the type of daytime incontinence. Chandra (1998) reported the responses to

583 questionnaires completed by families of children between 5 and 9 years of age and found that urinary urgency and pelvic tightening maneuvers to postpone voiding and prevent incontinence were the voiding issues most frequently reported. Urge incontinence was present in 7% of girls and 3% of boys (Chandra, 1998).

International

A study by Hellström and colleagues of 7-year-old Swedish children entering school revealed that 21% of girls and 18% of boys had moderate-to-severe urinary urgency. Daytime urinary incontinence occurred once weekly in 3.1% of girls and 2.1% of boys. A Japanese study of 6917 school-age children demonstrated an overall prevalence rate of 17.8% for OAB (Kajiwarara et al, 2006). Interestingly, this epidemiologic survey found a nearly equal prevalence of OAB between boys and girls of 19.1% and 16.6%, respectively. An Australian study addressed the frequency of voiding disorders in school-aged children (Sureshkumar et al, 2009). This study of 2856 students reported that 19.2% of children had experienced at least one episode of daytime incontinence in the previous 6 months, with 16.5% having experienced more than 1 wetting episode and only 0.7% experiencing wetting on a daily basis. Independent risk factors for daytime incontinence included nocturnal enuresis, female sex, history of UTI, and encopresis (Sureshkumar et al, 2009).

A large cross-sectional study of over 19,000 children between the ages of 5 and 13 was performed in the Republic of Korea and evaluated the prevalence of OAB by parental questionnaire (Chung et al, 2009). The overall prevalence of OAB was 16.6% and decreased with age from 23% to 12% by age 13 years (Chung et al, 2009). Compared with other children, those with OAB had a greater prevalence of nocturnal enuresis, constipation, fecal incontinence, UTI, delayed bladder control, and poor toilet facilities.

Gender and Age-Related Demographics

Robson (1997) and associates found that daytime incontinence varies with both age and gender. This group reported that the prevalence of daytime wetting at least once every 2 weeks was 10% in 5- to 6-year-old children, 5% from 6 to 12 years of age, and 4% from 12 to 18 years of age. In a population survey of 1192 individuals aged 1.5 to 27 years, daytime incontinence occurred in 13% of children aged 4 years, 7% of children aged 5 years, 10% of children aged 6 years, and 5% of children aged 7 years (Bloom et al, 1993). Studies on the prevalence of voiding disorders in school-age children indicate that daytime urinary incontinence is 2 to 5 times more common in girls (Sureshkumar et al, 2009). Hellström

and colleagues (1990) found that daytime incontinence was more common in girls (6.7%) than in boys (3.8%) and that most children with incontinence had other LUT symptoms (LUTS).

SELF-ESTEEM AND QUALITY-OF-LIFE ISSUES

Multiple epidemiologic and cross-sectional studies demonstrate that between 5% and 20% of children suffer with daytime incontinence (Hellström et al, 1990; Kajiwarra et al, 2004; Joinson et al, 2006; Sureshkumar et al, 2009). The reported incidence of incontinence ranges from 1.2% daily to 3.6% at least twice a week (Hellström et al, 1990). Remarkably, the majority of parents surveyed did not seek medical attention for their child's incontinence, and teachers recognized only 3% of the children in their classroom who actually suffered from daytime wetting (Sureshkumar et al, 2009). These statistics would make it appear that LUTD and its sequelae are of nominal consequence in the daily lives of young children. Various studies examining the impact of symptoms like urinary incontinence on self-esteem and quality of life in children would suggest otherwise.

Given the emerging recognition of patient perspectives in health care over the last decade, quality-of-life assessment is an important part of incontinence research. Measurement of quality of life in children with urinary incontinence gives a child-centric estimate of the impact that incontinence makes in daily life. In a survey study of 1185 children, both in the United States and Australia, school-age children were asked to grade the severity of 20 different stressful life events (Ollendick et al, 1989). Of the different situations examined, "Wetting pants in class" was rated as the third most stressful, which underscores the importance of urinary control in school-age children and their peers.

A recent article by Thibodeau and associates (2013) prospectively studied 40 children (10 males and 30 females), between 5 and 11 years of age with non-neurogenic daytime wetting. The Dysfunctional Voiding Symptom Score (DVSS), originally put forth by Farhat and colleagues (2000) was used to quantify the severity of LUTS and was completed by both parents and children. Parents and their children also completed the Pediatric Urinary Incontinence Quality of Life Score tool (PIN-Q), originally developed by Bower and coworkers (2006b), which measures the emotional impact that urinary incontinence has on a child. There was no statistically significant difference between parent and child scores for symptoms (DVSS) and quality of life (PIN-Q), indicating that parents were very aware of the child's symptoms and the impact they had. DVSS and PIN-Q responses were positively correlated (i.e., as DVSS scores increased the PIN-Q showed a corresponding rise).

COMORBIDITIES

Urinary Tract Infections

A clear and consistent relationship has been repeatedly demonstrated in multiple studies between LUTD and UTIs. What is unclear, however, is whether a causal relationship exists. This most likely is related to study design and interpretation. Bauer (2002) suggested that UTIs are not only an effect of dysfunctional voiding but also may precipitate the development of LUTD, specifically OAB.

Hellström and associates (1990) disseminated a questionnaire to analyze the micturition habits and UTI history to more than 3500 school-age children. Girls with daytime wetting, urgency, and emptying difficulties had a higher prevalence of a UTI history than those without symptoms. Hoebeke and colleagues (2001a) prospectively studied 1000 children during a 4-year study period with video-urodynamics to ascertain the cause and epidemiology of LUTD. The incidence of UTI was significantly higher in girls than in boys. In addition, boys with LUTD had no greater risk for UTI. In girls with underactive bladder there was a significantly higher incidence of UTI.

Chen and colleagues (2004) performed a multivariate analysis on 2759 children to elucidate the relationships among dysfunctional elimination, UTI, and VUR. Their data demonstrated a higher rate of LUTD in girls (43.7%) than in boys (23.8%), with 44% of children who had a history of UTIs also having concomitant LUTD. Interestingly, they observed no association of UTI or VUR individually, but rather found that LUTD was noted only when both UTI and VUR were present. This study challenges the contemporary paradigm espousing an independent association between UTI and LUTD.

In a recent retrospective review, Van Batavia and coworkers (2013) determined how many children who initially presented with LUTD had a history of UTIs. Of 623 children diagnosed with LUTD, one third had a history of UTIs, with the prevalence rate being significantly higher in girls than boys. When stratified by specific LUT conditions, girls with underactive bladder and dysfunctional voiding had the highest UTI rates. Not surprisingly, the association between UTIs and LUTD was most often noted for LUT conditions in which urinary stasis occurs.

Vesicoureteral Reflux

There is a known association between LUTD and VUR. Whether VUR is secondary to the LUT condition is controversial. Lapides and Diokono (1970) first described the association between dysfunctional voiding and VUR (Lapides and Diokono, 1970). Since that time a number of authors have expanded on the description and nature of the association. In the late 1970s, Koff and associates (1979) demonstrated that voiding against a closed sphincter can increase bladder pressure and may contribute to the development and persistence of VUR. The incomplete bladder emptying that occurs in children with LUTD can lead to urinary stasis with subsequent UTI causing inflammatory changes in the bladder wall that stimulate hypertrophy and overactivity. This is particularly true in older children who manifest with febrile UTIs after toilet-training has been completed. It has been theorized that detrusor hypertrophy can alter the closure mechanism at the ureterovesical junction, leading to reflux (Yeung et al, 1998).

One of the first studies to systematically address the relationship between LUTD and VUR was performed by Van Gool and associates (1992), who distributed a questionnaire to all children enrolled in the European arm of the International Reflux Study in Children. Extrapolating from the questionnaire results, the prevalence of dysfunctional voiding was approximately 18%. A strong association was observed between recurrent UTI and LUTD, and in those children with spontaneous resolution of their reflux, the prevalence of dysfunctional voiding was much lower.

Koff and associates (1998) reported their experience on 143 children with primary VUR who either resolved spontaneously or were surgically treated. LUTD was present in 66 (43% of the cohort), with 54 (82%) of these children having a breakthrough UTI and undergoing reimplantation compared to only 18% without LUTD. Of 70 children who had a breakthrough UTI, LUTD was present in 54 children (77%); in 73 patients who did not have a breakthrough infection, dysfunction was present in only 12 (16%) children. Additionally, if VUR resolution did occur, the time for resolution increased by 1.6 years in those with dysfunction compared to those without LUTD. Finally, unsuccessful surgical outcomes involving persistent, recurrent, and contralateral reflux occurred only in children with elimination disorders.

The association between LUTD and treatment failure after surgical correction for reflux has been borne out in a number of clinical studies. Regardless of surgical treatment modality (i.e., endoscopic vs. open reimplantation) ongoing LUTD has been shown to be associated with a higher failure rate. Capozza and colleagues (2002) treated a total of 320 children between 3 and 11 years of age with subureteral injection for grades II to IV VUR. They found untreated LUTD to be highly associated with endoscopic treatment failure at 6-month follow-up.

Targeted treatment for LUTD has been demonstrated to improve spontaneous resolution rates for VUR (Willemsen and

Nijman, 2000; Fast et al, 2013). In a recent study by Fast and coworkers (2013) patients diagnosed and treated for LUTD who had concomitant VUR at or near the time of diagnosis underwent targeted treatment for their specific dysfunction along with antibiotic prophylaxis. VUR was monitored with serial voiding cystourethrogram or video-urodynamics. After a mean of 3.1 years of treatment, VUR resolved with targeted therapy in 26 of 58 ureters. All of these patients had a history of UTIs before starting targeted intervention. Interestingly, they found that resolution rates for VUR were similar regardless of VUR grade. Resolution or significant improvement of reflux was greater in patients with dysfunctional voiding (70%) compared to those with OAB (38%) or underactive bladder (40%).

Psychological Associations

Recently, there has been an emerging awareness of the strong association that exists between neuropsychiatric comorbidities and LUTD in children. In fact, functional causes of LUTD are believed by many to originate from behavioral issues that evolve from personal stressors and/or adverse events that occurred around the time of toilet-training (Feldman and Bauer, 2006). If the LUTD is not addressed, this behavioral or learned response often will perpetuate itself. Limiting free access to a restroom or, worse, discouraging voiding in response to urgency in a child who has not developed complete cortical inhibition of voiding may alter normal coordination between bladder and sphincter (McKenna and Herndon, 2000).

Between 20% and 40% of children with daytime urinary incontinence are affected by comorbid behavioral disorders (von Gontard et al, 1998b; Joinson et al, 2006). Additionally, a number of epidemiologic studies have reported clinically significant behavioral problems in up to one third of children with enuresis (Hirasing et al, 1997; Liu et al, 2000). This is 2 to 4 times higher than children without enuresis and is comparable with rates of psychosocial problems in other pediatric chronic illness groups. Other studies have investigated the psychological problems associated with specific syndromes responsible for daytime urinary incontinence. These investigators found a higher rate of behavior problems in children with voiding postponement compared to those with urge incontinence as their major complaint (Lettgen et al, 2002; von Gontard et al, 2011a). Moreover, some have suggested that voluntary holding with postponement of voiding is acquired and may be reflective of ongoing behavioral issues (von Gontard et al, 1999).

Recently, Oliver and associates (2013) explored the prevalence of psychosocial comorbidities and their relationship to children presenting with LUTD (Oliver et al, 2013). Data were prospectively collected on patients 6 to 17 years of age. Parents completed a 21-question LUTS score based on a validated questionnaire and a psychosocial questionnaire that screened for stressful life events and psychological diagnoses. Of the 358 patients examined, 32% had a recent life stressor and 23% had a comorbid psychiatric disorder. Younger age correlated with a higher LUTS score. Children with a recent life stressor, psychiatric disorder, or the two comorbidities had a significantly higher LUTS score than children without comorbidities. This study lends support to the recommendation for screening of psychosocial comorbidities during the evaluation of pediatric LUTD.

In perhaps one of the largest epidemiologic studies to look at the association between daytime urinary incontinence and neuropsychiatric issues in children, researchers found a significantly increased rate of psychological problems among children who wet themselves compared to those who were dry (Joinson et al, 2006). Of the over 8000 children between 7.5 and 9 years of age who were studied, those with daytime wetting had significantly increased rates of attention-deficit/hyperactivity disorder (ADHD) (24.8%), conduct disorders (11.8%), separation anxiety (11.4%), and oppositional behavior (10.9%). The increased vulnerability to psychological problems in children with daytime urinary incontinence underscores the importance of parents seeking early intervention for the condition to help prevent later psychological problems. Moreover, clinicians should be cognizant of the association with

disorders such as ADHD in children with daytime wetting, because this is likely to interfere with treatment success.

Bowel Dysfunction

It has long been recognized that an intimate association exists between both hindgut and LUT function. Indeed, LUTS are seen in approximately 30% of children who present with constipation (Belman and Loening-Baucke, 1998). Previous reports have indicated a significant overlap in these conditions in the primary care setting, with nearly one quarter of children with functional fecal retention also reporting daytime urinary incontinence (Loening-Baucke, 2004). As one would expect, the prevalence of these comorbid conditions is even higher at tertiary care centers. Burgers and associates (2013a) recently reported that nearly half of patients seen at their pediatric urology clinic for LUTS also met criteria for functional constipation.

The relationship between abnormal bowel and bladder activity is termed *bowel-bladder dysfunction (BBD)* and is part of an entity originally described by Koff and colleagues (1998) as the *dysfunctional elimination syndrome*. The International Children's Continence Society discourages using the term *dysfunctional elimination syndrome* as this connotes a particular abnormality or condition (Austin et al, 2014). BBD is a more descriptive comprehensive term that does not necessarily explain pathogenesis but rather encompasses this parallel dysfunction. In any event, Koff recognized the significance of bowel dysfunction; if present, its clear identification and management were paramount if treatment of the LUT condition was to be successful. Koff and colleagues (1998) recommended that each LUT condition be treated specifically while at the same time addressing any concomitant bowel dysfunction, often before treatment of the LUT condition.

Although an exact pathophysiologic basis for BBD has not been clearly elucidated, a number of different theories have been put forth. One theory espouses that rectal distention from fecal retention puts direct pressure on the posterior bladder wall and that this constant force in turn leads to detrusor instability, which can precipitate bladder overactivity and impair efficient bladder emptying (Lucanto et al, 2000). A second theory assumes that both the urethral and anal sphincters share a common neural input. With chronic contraction of the anal sphincter from rectal stool impaction, the pelvic floor musculature similarly contracts inappropriately, leading to secondary detrusor-external urinary sphincter dyssynergia. This vicious cycle of discoordination is what is thought to induce bladder overactivity, urinary incontinence, recurrent UTIs, and VUR (O'Regan et al, 1985).

Please see the Expert Consult website for further details.

KEY POINTS: EPIDEMIOLOGY, SELF-ESTEEM AND QUALITY-OF-LIFE ISSUES AND COMORBIDITIES

- LUTD is commonly encountered in daily practice.
- Daytime incontinence varies with both age and gender in school-age children and seems to be more common in girls.
- There is a clear and consistent relationship between LUTD and UTIs, especially when urinary stasis occurs.
- There is a known association between LUTD and VUR. Continued LUTD is a risk factor for treatment failure after surgical correction for reflux. Targeted treatment for LUTD has been demonstrated to improve spontaneous resolution rates for VUR.
- Clinicians should be cognizant of the association between neuropsychiatric disorders and LUTD. Failure to adequately address these comorbidities is likely to interfere with treatment success.
- The relationship between abnormal bowel and bladder activity is termed *bowel-bladder dysfunction (BBD)*, and, if present, its clear identification and management is paramount if treatment of the LUT condition is to be successful.

In a recent study by [Burgers and colleagues \(2013a\)](#), researchers assessed the prevalence of functional defecation disorders in children referred to a tertiary pediatric urology outpatient clinic for LUTS. They analyzed the records of 113 patients between 4 and 17 years of age who presented with LUTS. Rome III criteria for functional constipation and functional nonretentive fecal incontinence were fulfilled by 47% and 11% of patients with LUTS, respectively. Not surprisingly, children with dysfunctional voiding were more likely to fulfill the criteria for functional constipation, while children with urge incontinence more often fulfilled the criteria for nonretentive fecal incontinence. This last point is intriguing in that it supports the notion that children with fecal incontinence and urge urinary incontinence often will not respond to a standard bowel program, which could potentially exacerbate the situation. Perhaps these children would be better served by a centrally acting agent to aid in suppression of overactivity or lack of inhibition. Clearly, there continues to be a void in our understanding of the bowel and bladder interaction in higher cortical centers and the spinal cord.

In a similar study by [Combs and associates \(2013\)](#), researchers sought to better illuminate the relationship between LUT and bowel dysfunction by studying 368 consecutive children who presented with LUTD. In a secondary analysis, they also sought to determine if constipation and encopresis, which are often presumed to coexist, also coexisted for their specific cohort. Overall, children with dysfunctional voiding had the highest incidence of bowel dysfunction, with constipation alone being the most frequently observed form. Somewhat surprisingly, nearly 50% of patients reporting encopresis did not have associated constipation. The majority of patients with encopresis with or without associated constipation had idiopathic detrusor overactivity, and those with the worst urgency were the ones reporting encopresis. Interestingly, in children with encopresis, severe urgency was commonly reported and after initiation of anticholinergic therapy the encopresis frequently resolved even before the urgency had fully subsided. This finding is similar to the results of [Burgers and colleagues \(2013a\)](#), and perhaps may be secondary to an overactivity of the detrusor and the rectal wall musculature, or a lack of inhibition of detrusor and rectal muscular activity. Whether this is a centrally mediated phenomenon is unclear.

TERMINOLOGY

The International Children's Continence Society (ICCS) is a global, multidisciplinary organization of clinicians involved in the care of children with LUTD (Austin et al, 2014). Perhaps one of the most significant impacts of the ICCS on the pediatric LUT function community was its initial terminology document (Névéus et al, 2006). Before the publication of this document, the nomenclature used in LUTD had been endemic with transposable terms that in some cases were not completely accurate and were often confusing. Moreover, this fostered uncertainty and made it rather difficult to compare research and study outcomes among different groups. The standardization of the nomenclature for pediatric and adolescent LUT function is thus critical in providing a platform for optimal comprehension and more effective interaction and treatment among multiple health care providers who care for these patients. Recently the ICCS revised the original terminology document to provide a current and consensus update reflecting refinement and current advancement of knowledge on pediatric and adolescent LUT function (Austin et al, 2014).

The terminology used for LUTS focuses on descriptive (as opposed to quantitative) language because quantitative data are currently lacking. Of particular relevance is the age of the child when applying terminology to describe pediatric LUT function. The reference point used by the ICCS is 5 years old or greater (4 years of age for bowel dysfunction), because this age is used by the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-V) (American Psychiatric Association, 2013) and the International Classification of Diseases 10 (ICD-10) to characterize urinary incontinence disorders (World Health Organization, 2008). The ICCS terminology document authors do stipulate, however, that there is variability and maturational aspects that certainly will affect LUT function and that there are, in fact, children who have voluntary control over LUT function under 5 years of age. As a result, it is at the discretion of the provider to selectively apply these terms in younger cohorts of children. (See "Terminology Document" by Austin and associates, 2014, for specific terms and their definition.)

DAYTIME URINARY INCONTINENCE AND BLADDER DYSFUNCTION

Evaluation

Evaluation of the child or adolescent with suspected voiding dysfunction commences with a detailed and thorough history and physical examination. The goals of evaluation are first and foremost to determine whether the patient has a filling or emptying (or both) phase abnormality. If an abnormality is found, the evaluation should then be directed toward determining the underlying cause and distinguishing whether the dysfunction stems from an anatomic or functional issue. This last point is critical because the management strategy will depend on the cause.

History

A thorough history is going to be invaluable in ascertaining whether and what type of bladder dysfunction is present. In general, the history should be taken from the child if possible (as opposed to caregivers) and tailored to the maturational age and stage of development of bladder and bowel control. Our approach has been to first focus on the identification of a possible anatomic or neurologic source to explain a patient's current symptomatology and, once this has been ruled out, to distinguish which form of bladder dysfunction is present. Vital components of the history often will include voiding schedule, symptomatology, bowel habits, family history, maternal prenatal history, perinatal history, developmental milestones, toilet training, neuropsychiatric comorbidities, medical/surgical history, social history, diet, and previous UTIs.

Bladder and Bowel Diaries

Perhaps one of the most helpful diagnostic tools in the armamentarium of providers who care for children with LUTD is the voiding diary. Its usefulness stems from the fact that this log is an objective record of the child's bowel habits and urinary voiding pattern. The diary should include voided volumes, timing of each void and incontinent episode, timing of each bowel movement and fecal soiling episode, and fluid intake.

In the evaluation of LUTD, the frequency/volume chart is a diary recording fluid intake and urine output during a 24-hour period (Bower et al, 1997; Hoebeke et al, 2010). It can be used for both diagnostic and therapeutic purposes. For diagnostic purposes, the chart should cover at least 48 hours and not necessarily recorded on 2 consecutive days (Austin et al, 2014). Episodes of urgency and urine loss also should be recorded. Urine loss is quantified by recording if clothing had to be changed after the urine loss (significant urine loss) or not. The chart gives information about fluid intake, number of voids, voided volume, and urine loss (Fig. 143-1). We also employ a 7-day bowel diary that uses the Bristol Stool Form scale (Lane et al, 2011) in ruling out BBD. Although controversy surrounds the best way to diagnose functional constipation in children, the ICCS recommends the use of the Rome III criteria (Rasquin et al, 2006).

Questionnaires

Questionnaires in the evaluation of LUT function have emerged as useful tools to more objectively translate somewhat subjective complaints into semiquantitative data (Akbal et al, 2005). These scoring systems not only allow providers to more accurately gauge the extent of LUTD but also provide a method of monitoring outcomes during treatment (Afshar et al, 2009). The two main types of questionnaires that have emerged for pediatric LUTD are measurements of LUT function and psychological screening.

Dysfunctional Voiding Symptom Score

In 2000, Farhat and colleagues (2000) reported on the creation of the DVSS based on the International Prostate Symptom Score for benign prostatic hyperplasia. The DVSS was the first scoring system of its kind and has been used in a variety of clinical settings. There are 10 quantitative and qualitative urologic parameters translated into age-appropriate questions for children regarding urinary symptoms, such as urinary incontinence, voiding habits, urgency, posturing, bowel habits, and stressful life conditions. The 10 questions were assigned scores of 0 to 3 according to incidence in the month before responding to the questionnaire and responses are weighted equally, giving a maximum possible score of 30 (Fig. 143-2).

Pediatric Urinary Incontinence Quality of Life Score

The Pediatric Urinary Incontinence Quality of Life Score (PIN-Q), developed by Bower and colleagues (2006b) measures the emotional impact that urinary incontinence has on a child. This cross-cultural urinary incontinence quality-of-life tool has been found to have excellent test-retest reliability and validity (Bower et al, 2006a). It consists of 20 questions related to urinary incontinence quality of life that are graded on a scale of 0 to 4 (0 = No, 1 = Hardly ever, 2 = Sometimes, 3 = Often, 4 = All the time) with a total possible score of 80. The total score indicates the impact urinary incontinence has on the child's quality of life, with the higher score indicating a more significant effect. Both the PIN-Q and DVSS questionnaire have been found to be complementary and provide a clinically appropriate picture of LUTD and its impact on a child's quality of life (Thibodeau et al, 2013).

Psychological Screening

It is well documented that children with BBD have a high rate of comorbid behavioral and emotional disorders. In several

Patient name

INTAKE AND VOIDING DIARY

Instructions: Begin recording as soon as you wake in the morning and continue for 24 hours. Choose 2 full days to complete this record—note that they DO NOT need to be consecutive, but just days that you can be sure to record EVERY void. Please measure voided volumes in the hat provided in 'cc' and fluid intake in 'oz.' Please record approximate times for all events, and try to note the severity of urinary leakage and if there is any associated urgency.

[illegible]

Figure 143-1. Daytime frequency and volume chart for 48 hours.

representative studies 20% to 30% of children with enuresis, 20% to 40% with urinary incontinence, and 30% to 50% with fecal incontinence are affected by comorbid behavioral disorders (Tekgul et al, 2009; von Gontard et al, 2011). The principle behind psychological screening is that the same care used by the provider to exclude organic causes of LUTD should be applied to the assessment of behavioral aspects. Therefore all health care professionals who work with children with BBD should possess a basic understanding of psychological principles to treat their young patients adequately.

Child Behavior Checklist

The Child Behavior Checklist (CBCL) is a parental questionnaire on which children are rated on various behavioral and emotional problems (Achenbach and Ruffle, 2000). It has been one of the most widely used standardized measures in child psychology for evaluating maladaptive behavioral and emotional problems in preschool subjects aged 18 months to 5 years and in subjects between the ages of 6 and 18 years. The preschool checklist contains 100 questions and the school-age checklist contains 120 questions, with responses recorded on a Likert scale. It assesses internalizing (i.e., anxious, depressive) and externalizing (i.e., aggressive, hyperactive) behaviors. Several subareas are also measured, including somatic complaints, anxiety, depression, destructive behavior, social problems, thought problems, attention problems, aggressive behavior, and delinquent behaviors.

Short Screening Instrument for Psychological Problems in Enuresis

The Short Screening Instrument for Psychological Problems in Enuresis (SSIPPE) is a brief instrument derived from seven items of the Internalizing scale of the CBCL and six items of the Attention Deficit Hyperactivity Disorder scale of the Disruptive Behavior Disorders Rating scale (Van Hoeckel et al, 2007). At a minimum, a short validated screening questionnaire such as the SSIPPE (or CBCL)

should be completed by every parent of a child who presents with LUTD. If no problem items are checked and no obvious behavioral problems have become apparent during the initial assessment, the recommendation is to concentrate on treatment of BBD only. If more than two "Yes" items per section (SSIPPE) are checked, parents should fill out a long validated questionnaire such as the CBCL. Should the CBCL demonstrate a significant behavioral or emotional issue, a full child psychological assessment ought to follow.

Physical Examination

The physical examination is focused on genitourinary anatomy and neurologic function. Related to anatomy and critical in the initial evaluation of children with suspected BBD is the appearance of their undergarments. For instance, yellow stains in the underwear may be an indicator of urge or overflow incontinence or postvoid dribbling. Stool soiling of the underwear is also important and can denote a spectrum of gastrointestinal dysfunction, from functional constipation to encopresis.

Abdominal Examination

As previously stated, constipation is one of the most common signs of bowel dysfunction in children and adolescents presenting with BBD. Examination of the abdomen is critical in determining whether stool is present in the colon. In a child with constipation, the abdominal examination may detect tenderness of the left upper and lower quadrants resulting from colonic distention secondary to fecal impaction and/or gaseous distention.

Back and Spinal Examination

In the overwhelming majority of cases, examination of the lower back and spine will reveal a normal-appearing back and anocutaneous folds. Regardless of the incidence, however, **special attention should always be paid to the lower back for cutaneous manifestations of an occult spinal dysraphism or sacral agenesis**

Figure 143-3. Occult spina bifida in a child with a sacral dimple. (Courtesy Elaine Fonseca, MD.)

(Fig. 143-3). These include an asymmetrical gluteal cleft, a presacral dimple, a lipoma, a hair tuft, a dermal sinus tract, and a dermal vascular malformation. In general, these lesions should be evaluated with magnetic resonance imaging of the lumbar and sacral spine.

Genital Examination

In boys, the examination necessarily includes inspection of the urethral meatus to detect possible meatal stenosis. Although direct inspection of the meatus may be sufficient, our preference has been to observe the urinary stream directly during voiding to note its caliber and direction because this entity is not a true stenosis but rather a ventral urethral membrane that deflects the urinary stream upward (Fig. 143-4). Almost invariably, meatal stenosis is seen in circumcised boys because the prepuce is thought to protect the meatus from chronic irritation and subsequent epithelialization of this ventral meatal web of tissue. Epididymoorchitis sometimes can be seen in males with dyssynergic voiding. The theory is that increased bladder pressures can lead to retrograde reflux of caustic urine into the ejaculatory ducts, leading to inflammation along the course of the vas deferens, epididymis, and testes.

In girls, deformities of the urethral meatus also have been noted to be associated with LUT voiding dysfunction (Hoebeke et al, 1999; Klijn et al, 2012). The theory is that girls with certain anomalies of the urethral meatus (i.e., a ventral web of tissue akin to meatal stenosis in males) predispose to an anterior deflected urinary stream and so they cannot void in the ideal toileting position. This then results in lower success rates for behavioral training programs. Hoebeke and colleagues (1999) demonstrated that young females with meatal deformities were diagnosed with more severe forms of dysfunctional voiding on urodynamic investigation compared to a control group. They also showed improved micturition patterns and fewer symptoms after surgical correction. This finding

Figure 143-4. Meatal stenosis with an inferior web of tissue that results in an upward urinary deflection.

was corroborated in a second study by [Klijn and associates \(2012\)](#), who found that 39% of female patients with dysfunctional voiding reported an anteriorly deflected urinary stream. After surgical correction, they found that half of these girls were free of all related symptoms and required no further behavioral training. Examination of the labia and vaginal introitus is performed to detect any evidence of labial adhesions. Although labial adhesions are often purported to be a cause of bladder outlet obstruction (BOO), this has rarely been the case in our experience, unless they are dense enough to require surgical division. More often, as the labia minora adhere (usually from posterior to anterior) the resultant pouch sequesters small amounts of urine that may dribble into the underwear between voids, depending on the child's posture. The stagnant urine in the pouch predisposes to asymptomatic bacteriuria and UTI ([Leung and Robson, 2004](#)). The problem is usually self-limited at around the time of puberty because the presence of estrogen has a protective effect ([Leung and Robson, 2004](#)). Areas of skin excoriation or redness may be present and are often a sign of continuous or severe urinary leakage with chronic inflammation and less often secondary to fungal infection.

Neurologic Examination

A focused neurologic examination should include assessing lower extremity strength and deep tendon reflexes, gait, perineal and anal sensation, and rectal tone. The anocutaneous reflex (i.e., “anal wink”) and bulbocavernosus (Osinski) reflex should be assessed to denote any interruption of the sacral reflex arcs (S2 to S4). Any abnormality of the neurologic examination may be indicative of a neurologic lesion that also affects the function of the bladder and should be assessed with proper spinal imaging.

Investigative Tools

Urinalysis

The single most important and perhaps only laboratory test that should be performed in all children who present with LUTD is the urinalysis. This screening test will invariably aid in deciphering whether the child's symptomatology is due to a bona fide UTI or is merely dysuria associated with BBD. **Particularly important elements of the urinalysis include specific gravity and the presence of white or red blood cells, bacteria, protein, and glucose.** A low specific gravity may be secondary to a renal concentrating defect and often will lead to polyuria. White blood cells (WBCs) suggest infection and/or inflammation. Red blood cells (RBCs) generally denote infection when found with WBCs; however, isolated RBCs can be found in children with LUTD secondary to storage and

voiding dynamics. Isolated proteinuria is common in children and may represent a benign condition or a serious underlying renal disease or systemic disorder. Depending on the degree of proteinuria, consideration should be given to obtaining a serum creatinine level to estimate the glomerular filtration rate. Significant glucosuria clinches the diagnosis of diabetes mellitus and often will lead to significant polyuria.

Urine Culture and Sensitivity

A urine culture sample should be obtained if there is evidence of a bona fide UTI. We generally would not recommend performing urine cultures reflexively on all patients, because this practice will undoubtedly identify patients with simple bacterial colonization and has the potential to foster bacterial resistance and infection with more virulent organisms if treated.

Uroflowmetry

Uroflow studies consist of measuring the velocity of urinary flow (volume voided per unit time) and examining the pattern during urination into a uroflowmeter. The child voids into a collection device that produces a urinary flow curve providing the maximum (Qmax) and average (Qavg) urinary flow rates, voided volume, flow time, and shape of urine flow. Uroflowmetry may be done concomitantly with electromyography (EMG) testing of the pelvic floor musculature and external urethral sphincter by affixing pads to the perineum. **The advantage of combining EMG with uroflowmetry is the ability to appreciate synergy or dyssynergy between the bladder and the pelvic floor–sphincter complex.**

Qmax is the most relevant quantitative variable when assessing bladder outflow. Sharp peaks in the curve are usually artifacts, so maximum flow rate should be registered only when a peak level has a duration of longer than 2 seconds ([Szabo et al, 1995](#)). In studies of normal children and adults, a linear correlation has been found between maximum flow and the square root of voided volume ([Chang et al, 2013](#)). If the square of the maximum flow rate ($[mL/s^2]$) equals or exceeds the voided volume (milliliters), the recorded maximum flow is most likely normal.

There are a few caveats that should be mentioned. **First, to obtain an interpretable uroflow, a child must be toilet-trained.** **Second, uroflowmetry provides information regarding the emptying phase of the bladder only and gives no information about what is happening during filling.** **Third, it is important that the volume of voided urine is adequate, because curves change when the voided volume is less than 50% of expected bladder capacity for age** ([Austin et al, 2014](#)). Finally, it is critical to obtain more than one curve to improve the accuracy, reliability, and interpretation of the test.

Uroflowmetry provides readily useful information regarding the pattern or shape of urine flow curve that often can be diagnostic of an underlying cause. In fact, obtaining an adequate uroflow pattern along with a coherent history and physical examination often can obviate the need to pursue more invasive urodynamic testing, which should be performed only when the diagnosis is unclear. The precise shape is determined by detrusor contractility and influenced by abdominal straining, coordination with the bladder outlet musculature, and any anatomic obstruction. The ICCS has developed categories for what is considered normal and abnormal, with five types of urine flow patterns identified ([Fig. 143-5](#)). Each specific pattern is no guarantee of an underlying diagnostic abnormality but rather serves as a guide to the existence of a specific condition.

Bell-Shaped Curve. The urinary flow curve of a healthy child should register as a smooth *bell-shaped* curve regardless of gender, age, and voided volume.

Tower-Shaped Curve. The tower-shaped curve is a sudden, high-amplitude curve of short duration that suggests an OAB produced by an explosive voiding contraction. It should be noted, however, that children with OAB may have a bell-shaped curve because this LUTD is mainly related to the filling phase of the bladder.

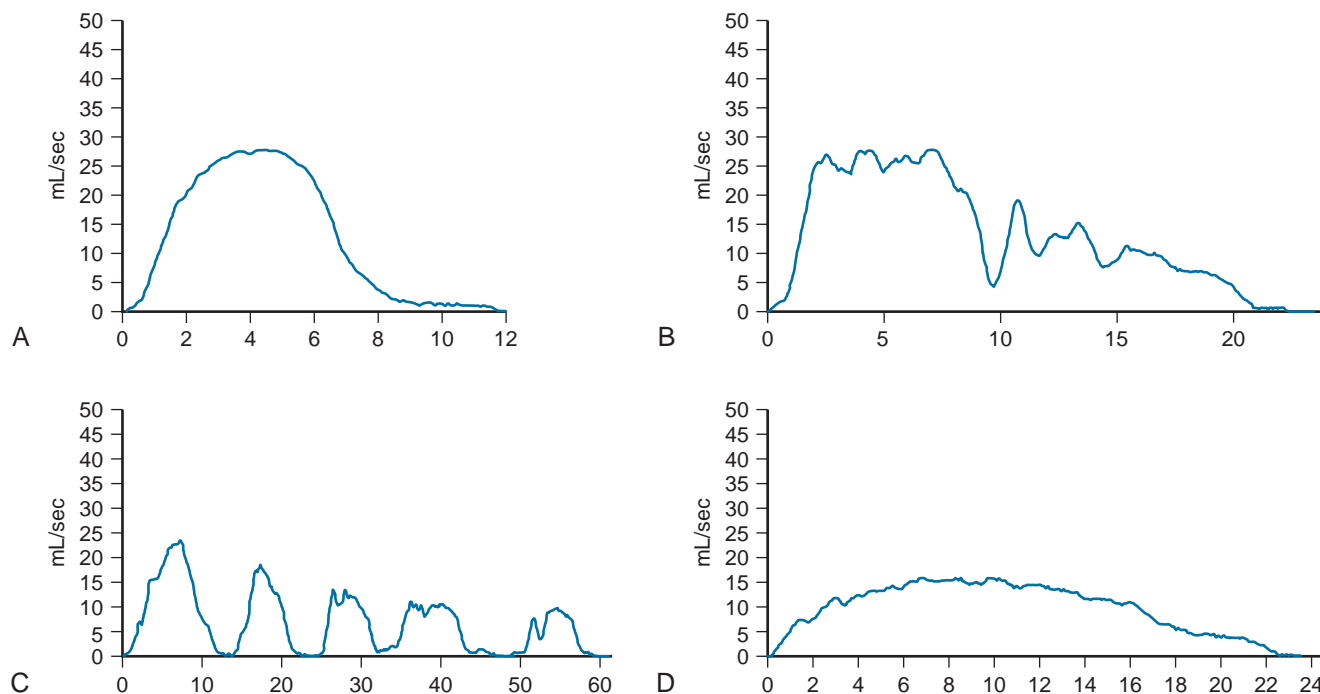

Figure 143-5. Common uroflow patterns. A, Bell shaped. B, Staccato. C, Interrupted. D, Plateau. (From Austin PF, Bauer SB, Bower W, et al. The standardization of terminology of lower urinary tract function in children and adolescents: update report from the Standardization Committee of the International Children's Continence Society. *J Urol* 2014;191:1863-5.)

Staccato-Shaped Curve. The staccato-shaped pattern is irregular and fluctuating throughout voiding, but the flow is continuous and never reaches zero during voiding. This pattern suggests intermittent sphincter overactivity during voiding and is often associated with dysfunctional voiding. It will be seen as sharp peaks and troughs in the flow curve. To qualify for a staccato label, the fluctuations should be larger than the square root of the maximum flow rate.

Interrupted-Shaped Curve. This flow curve will display discrete (albeit low amplitude) peaks similar to a staccato-shaped curve; however, there will be segments where the flow rate is zero with complete cessation of urinary flow between these peaks. This flow pattern suggests an underactive bladder because each peak represents abdominal muscle straining (i.e., Valsalva) creating the main force for urine evacuation. In between each strain, the flow ceases as a result of an absent or weak detrusor contraction. It is possible this flow pattern can be seen with dyssynergy between the bladder and external urethral sphincter, and a concomitant EMG and/or pressure flow study often will be useful to distinguish between the two.

Plateau-Shaped Curve. The plateau-shaped curve is a flattened, low-amplitude prolonged flow curve that is suggestive of BOO. The BOO can be anatomic (e.g., posterior urethral valves or urethral stricture) or dynamic (e.g., continuous, tonic sphincter contraction). Flow EMG may differentiate among BOO subtypes. A plateau-shaped curve may be seen with an underactive bladder during a long continuous abdominal strain. Abdominal pressure monitoring during the uroflow can help delineate an underactive bladder condition.

Pelvic Ultrasound

Pelvic ultrasound is a key tool in the evaluation of pediatric LUT function and is used in the initial evaluation of all children with suspected BBD at our institution (Fig. 143-6). In addition to giving objective information about the voiding pattern of the child in question, it can be readily used to monitor progress over time.

Figure 143-6. Pelvic ultrasound demonstrating a thickened bladder wall and a large amount of stool in the rectum.

Ultrasonography can calculate bladder volume and thus is useful in measuring prevoid and postvoid residual (PVR) urine volume and anatomic details of the bladder and rectum (e.g., bladder wall thickness, stool, rectal distention).

Postvoid Residual

PVR measurements in neurologically intact children are highly variable with significant intraindividual variability. Chang and Yang (2009) suggested that abnormal PVR urine volume could be defined as a PVR greater than 20 mL (as opposed to >10% of estimated bladder capacity) on repeat micturitions without bladder

overdistention. Recently, investigation of 1128 healthy Taiwanese children between 4 and 12 years of age with a bell-shaped uroflow pattern and a voided volume of greater than 50 mL support the following normative 95th percentile values for an abnormally elevated PVR (Chang et al, 2013):

- **Children 4 to 6 years:** Single PVR greater than 30 mL or greater than 21% of bladder capacity (BC), where BC is determined as voided volume (VV) + PVR and expressed as percent of the expected bladder capacity ($EBC = [age\ (yr) + 1] \times 30\ mL$). It is recommended that a repeat PVR be performed with dual measurements; a repetitive PVR greater than 20 mL or greater than 10% BC is considered significantly elevated.
- **Children 7 to 12 years:** A single PVR greater than 20 mL or 15% BC or repetitive PVR greater than 10 mL or 6% BC is considered elevated.

According to Chang and colleagues (2013), standard conditions should be applied to measuring PVR; the bladder should not be underdistended (<50%) nor overdistended (>115%) in relation to the EBC; PVR must be obtained immediately after voiding (<5 minutes). Further validation is needed for these nomograms in similar cohorts across cultures.

Bladder Wall Thickness

In daily clinical practice a thickened bladder wall should alert the clinician to long-standing problems with urine storage and emptying. The bladder wall is normally less than 3 mm when full and less than 5 mm when relatively empty (Jequier and Rousseau, 1987). A thickened bladder wall is suggestive of an anatomic or functional outlet obstruction causing detrusor hypertrophy; however, the most common diagnosis associated with a thickened bladder wall was found to be OAB (Yeung et al, 2007). Bladder wall thickness can be measured with either a full or an empty bladder and is inversely proportional to the degree of bladder filling.

Please see the Expert Consult website for further details.

Rectal Distention

Although there is insufficient evidence to support the notion that the transverse diameter of the rectum alone can be used as a predictor of constipation and fecal impaction, a number of authors have made several observations on this subject (Fig. 143-7). Klijn and associates (2004) measured the diameter of the rectum on bladder ultrasonography in a constipated group of patients with dysfunc-

Figure 143-7. Pelvic ultrasound showing a dilated rectum filled with stool compressing posterior wall of bladder.

tional voiding and compared this diameter in a control group of patients with a normal defecation pattern. Not surprisingly, in the group of constipated patients with dysfunctional voiding, the diameter of the rectum was significantly larger than in the control group.

Please see the Expert Consult website for further details.

Bristol Stool Scale

The Bristol Stool Scale or Bristol Stool Chart is a useful guide designed to classify the form of human feces into seven distinct categories. Sometimes referred to in the United Kingdom as the Meyers scale, it was developed at the University of Bristol in 1997 (Lewis and Heaton, 1997). The seven types of stool (ranging from most firm in type 1 to loosest in type 7) are as follows (Fig. 143-8):

- **Type 1:** Separate hard lumps, like nuts (difficult to pass because stool has not retained any water)
- **Type 2:** Sausage-shaped, but lumpy; represents multiple type 1 stools congealed into a single mass, typical for functional constipation
- **Type 3:** Like a sausage but with cracks on its surface
- **Type 4:** Like a sausage or snake, smooth and soft, typical for someone who has a daily bowel movement
- **Type 5:** Soft blobs with clear-cut edges, passed easily, usually multiple times per day
- **Type 6:** Fluffy pieces with ragged edges, a mushy stool, urge to defecate can be difficult to control
- **Type 7:** Watery, no solid pieces, entirely liquid

We prefer to use it as a clinical communication aid with our patients and their families in terms of what to strive for and to facilitate titration of supplemental fiber or laxative administration.

BRISTOL STOOL SCALE		
Type 1		Separate hard lumps, like nuts (hard to pass)
Type 2		Sausage-shaped but lumpy
Type 3		Like a sausage but with cracks on its surface
Type 4		Like a sausage or snake, smooth and soft
Type 5		Soft blobs with clear-cut edges (passed easily)
Type 6		Fluffy pieces with ragged edges, a mushy stool
Type 7		Watery, no solid pieces. Entirely liquid

Figure 143-8. Bristol Stool Chart. (Modified from Lewis SJ, Heaton KW. Stool form scale as a useful guide to intestinal transit time. Scand J Gastroenterol 1997;32:920-4.)

In 2004, Yeung and colleagues reported on their evaluation of a special bladder ultrasound protocol for the assessment of LUTD compared with urodynamic findings and for the prediction of treatment outcome in children with enuresis (Yeung et al, 2004b). The bladder volume wall thickness index (BVWI) was a ratio of bladder volume to wall thickness, and they found statistically significant correlations between BVWI and enuresis treatment response. In addition, there was a high predictive value of normal bladder function as evaluated by urodynamics with a normal BVWI. Although it is intuitive that bladder wall thickness would correlate with LUTD, not all groups have come to the same conclusion (Mostafavi et al, 2012).

Recently, Burgers and colleagues (2013b) took a group of 84 children with a median age of 9 years (range 6 to 11) and performed both transabdominal ultrasound and digital rectal examination (DRE) under anesthesia. A rectal mass was found on transabdominal ultrasound and DRE in 32% and 41% of all children, respectively, with agreement between the two tests in 82.5%. The median diameter of the rectum was 3.3 cm in children with a full rectum and 2.5 cm and 2.0 cm in patients with a half-filled and empty rectum, respectively. They concluded that transabdominal ultrasound was a noninvasive and reliable alternative to assess the rectal filling state and might replace DRE in the evaluation of children with constipation.

KEY POINTS: EVALUATION OF DAYTIME URINARY INCONTINENCE AND BLADDER DYSFUNCTION

- The goals of evaluation are to determine whether the patient has a filling or emptying (or both) phase abnormality. If an abnormality is found, the evaluation then should be directed toward determining the underlying cause and distinguish whether the dysfunction stems from an anatomic or functional issue.
- Vital components of the history include voiding schedule, symptomatology, bowel habits, family history, maternal prenatal history, perinatal history, developmental milestones, toilet training, neuropsychiatric comorbidities, past medical/surgical history, social history, diet, and previous UTIs.
- The voiding diary is one of the most helpful diagnostic tools in the armamentarium of providers who care for children with LUTD.
- During physical examination, special attention should be paid to the lower back for cutaneous manifestations of occult spinal dysraphism.
- All children presenting with LUTD should provide a urinalysis with important elements of the urinalysis, including the specific gravity and the presence of white or red blood cells, bacteria, protein, and glucose.
- Uroflowmetry provides readily useful information regarding the pattern or shape of urine flow curve that can often be diagnostic of an underlying cause. Qmax is the most relevant quantitative variable when assessing bladder outflow.
- Ultrasonography can calculate bladder volume and thus is useful in measuring prevoid and PVR urine volume and can provide useful anatomic details of the bladder and rectum (e.g., bladder wall thickness, stool presence, rectal distention).

Treatment

The ICCS has published treatment guidelines on various LUT conditions and their associated comorbidities (Chase et al, 2010; Hoebeke et al, 2010; Franco et al, 2013; Burgers et al, 2013c; Austin et al, 2014). The management of a child or adolescent who suffers from LUTD is primarily directed at improving symptoms (e.g., urinary and/or fecal incontinence, recurrent UTIs) and protecting the upper urinary tract from permanent damage. Methods for treating children with BBD must be tailored to the specific LUTD and the child's symptomatology. Therapeutic considerations include the underlying cause, patient age, motivation and maturity level, symptom severity and duration, prior interventions, and potential risk factors for upper urinary tract damage (i.e., elevated intravesical storage pressures, VUR, recurrent UTIs).

We use a stepwise approach to the treatment of children presenting with symptoms concerning for BBD (Thom et al, 2012). Our algorithm generally moves from least to most invasive with conservative measures (e.g., treatment of constipation, behavioral modification) exhausted before initiating medications, physical therapy, biofeedback, neuromodulation, or surgical intervention.

According to the ICCS, researchers and/or clinicians should recognize three basic principles of treatment outcomes (Austin et al, 2014). First, the symptom frequency during baseline and after treatment should each be documented. Second, the assessment of treatment response must be based on pretreatment baseline registration symptom frequency. Third, the response during treatment should be noted, as well as the response after cessation of treatment for a specified period; and these two responses may not be the same. This has been outlined as follows:

- **Initial success** (based on symptom frequency)
 - No response: Less than 50% reduction
 - Partial response: 50% to 99% reduction
 - Complete response: 100% reduction

- **Long-term success**

- Relapse: More than one symptom recurrence per month
- Continued success: No relapse in 6 months after cessation of treatment
- Complete success: No relapse in 2 years after cessation of treatment

Urotherapy

Urotherapy is conservative-based therapy and treatment of LUTD that rehabilitates the LUT and encompasses a very wide field of health care professionals (Austin terminology document [Austin, 2014]). It primarily involves behavioral modification of voiding (i.e., timed voiding schedules), lifestyle modifications, and treatment of constipation. Although there are no randomized, controlled trials comparing the efficacy of conservative intervention to other therapies, several retrospective studies suggest a reduction in symptoms of up to 70% with a strictly conservative approach (Wiener et al, 2000; Allen et al, 2007).

Urotherapy can be divided into standard therapy and specific interventions. **Standard components** include the following:

1. *Information and demystification.* It is often helpful to explain normal LUT function to parents and children and how the particular child deviates from normal.
2. *Instruction* on how to resolve LUTD (i.e., behavioral modification, timed voiding, treatment of constipation).
3. *Lifestyle advice.* Encompasses balanced fluid intake and diet modification; diminished dietary irritants such as caffeine, carbonation, citrus, chocolate, and spicy foods; regular bladder and bowel emptying patterns; and skin care for those with perineal irritation from incontinence. It is also helpful to review optimal posture during voiding (i.e., sitting in the middle of the toilet with heels flat on the ground or supported on a footstool). One useful aid to teach correct upright posture is to have children straddle the toilet seat and face the toilet bowl during voiding, because this spreads the legs apart (preventing holding maneuvers such as forcefully crossing the legs) and forces them to straighten the back as they balance themselves on the toilet seat. This maneuver also can be used to successfully correct vaginal reflux.
4. *Registration* of symptoms and voiding habits, using bladder diaries or frequency-volume charts and potentially mobile applications.
5. *Support and encouragement* via regular follow-up with the caregiver.

Specific interventions of urotherapy include various forms of pelvic floor muscle retraining (i.e., biofeedback), neuromodulation, and intermittent catheterization.

Conservative Management

Bowel Dysfunction

One of our first steps is to decipher whether concomitant bowel dysfunction exists based on history, physical examination, and pelvic ultrasound. As mentioned previously, anorectal and LUT function are closely interrelated. If evidence of bowel dysfunction is indeed present (as is often the case), we generally initiate a bowel regimen that includes high fiber and increased fluid intake. Our rule of thumb for **daily fiber intake** is **age in years + 15 to 20 for total number of grams to be ingested**. Parents are reminded that **without concurrent increased fluid intake, increased fiber could actually make matters worse by allowing smaller stool balls to bind together and subsequently increase the severity of their child's constipation**.

If increased fiber is not a feasible solution, we usually recommend titrating polyethylene glycol such that children are eventually having daily Bristol type 4 stools. In severe cases, we recommend a complete bowel cleanse (i.e., chemical disimpaction) consisting of what we term "magic mousse" supplementing with tap water enemas to relieve any distal obstruction by impacted stool in the

rectal vault. Magic mousse consists of three simple ingredients: 1 cup ice cream, 1 cup prepared pudding, 6 oz. mineral oil, that are mixed and frozen (Campigotto, personal communication, 2014). Children younger than 6 years of age are given 4 T twice daily and those 6 years of age or older get double the dose twice daily. This is generally done over a weekend for children who are in school or daycare because this routine is fairly intense and children may have multiple, somewhat unpredictable bowel movements. **It is imperative that the bowel regimen be continued throughout the treatment course to both maximize therapeutic efficacy for the bladder dysfunction component and counteract the constipating side effect of anticholinergic medications.**

The importance of addressing constipation in those with BBD is substantiated by the findings of a large retrospective study of 234 chronically constipated and encopretic children who were treated for constipation and reassessed at least 12 months after initiation of therapy (Loening-Baucke, 1997). Of these children, 29% complained of daytime urinary incontinence and 34% had enuresis. UTI was present in 11% of the cohort and was more common in girls. **Relief of constipation resulted in disappearance of daytime urinary incontinence in 89% and enuresis in 63% of patients. There were no reported UTIs in any patient who had no anatomic abnormality of the urinary tract.**

Behavioral Modification

The ultimate goal of any structured behavioral modification program is to return the child to normal micturition habits. With this goal in mind, it is important to set an individualized voiding regimen to establish a consistent voiding routine. **The classic regimen entails timed voiding with frequent voids scheduled every 2 hours during the day.** This strategy is crucial in aiding to avoid bladder overactivity and urge symptoms, which can occur as the bladder fills and begins to reach the critical volume that triggers the urge to void. We recommend wristwatch alarms to all patients because these can readily assist older, more independent children to comply with timed voiding (Hagstroem et al, 2010). The use of a vibratory watch is also a good option because it does not disturb peers, with only the patient knowing that it has indicted the set time. Regardless of what regimen is used, children are encouraged to urinate before they have a sense of urgency, empty their bladders completely, and avoid abdominal straining.

The timed voiding regimen is often linked to a positive reinforcement program using a diary in which the child tracks the number of times voided during the day. It has been demonstrated that the establishment of a reward system can significantly improve the child's self-esteem and compliance (Allen et al, 2007). Specifically, the incentive scheme should focus on rewarding the child for following the recommended program (e.g., stickers each time the child voids during the day) as opposed to "not wetting" themselves. Not surprisingly, behavioral modification has been shown to be more successful in older children (older than 8 years of age), who, in general, will be more motivated by peer pressure and are mature enough to respond to and follow instruction (Curran et al, 2000; Heilenkötter et al, 2006).

Biofeedback

Biofeedback is a treatment modality that uses electronic or mechanical instruments to relay perceptual evidence to assist a person in gaining control over a physiologic process or function (Liberati, 2005). This method has been used for over three decades in the urologic setting and employs noninvasive urodynamic instrumentation to measure, record, and provide direct, instantaneous information to the child about voiding function (Maizels et al, 1979). Real-time uroflowmetry allows the patient to observe the urine flow rate. Concurrent placement of adhesive pads on the perineum measures sphincter and/or pelvic floor activity. Abdominal EMG also can be performed if desired. Each session lasts approximately 45 minutes with a trained practitioner overseeing therapy. The visual and auditory feedback allows the child to become aware of and gain

control over LUT function by teaching them how to voluntarily relax their sphincter and pelvic floor musculature during voiding, thus preventing detrusor-sphincter dyscoordination. In fact, many biofeedback programs have been tailored to children by using interactive computer games controlled by pelvic floor contraction and relaxation along with urinary flow rate (McKenna et al, 1999). This system has facilitated the training process and lowered the age at which children can be successfully treated; however, one should bear in mind that most children under 5 years of age are typically incapable of receiving biofeedback regularly.

A number of observational studies have documented the utility of biofeedback therapy in reducing the symptoms associated with LUTD (Yamanishi et al, 2000; Chin-Peuckert and Salle, 2001; Nelson et al, 2004; Klijn et al, 2006), expediting the resolution of VUR (Palmer et al, 2002; Kibar et al, 2007), and eliminating recurrent UTIs (Nelson et al, 2004). Recently, a systematic review evaluated the efficacy of biofeedback in the treatment of children with BBD (Desantis et al, 2011). The review included 27 studies (1 randomized controlled trial and 26 case-series). The pooled estimate showed an 83% and 80% improvement in UTI and daytime urinary incontinence, respectively. The only included randomized study favored biofeedback over standard urotherapy (relative risk [RR] 1.4, 95% confidence interval [CI] 0.98 to 2), but this was not statistically significant. On analysis of all included studies, there also was improvement in constipation (18% to 100%), frequency (67% to 100%), urgency (71% to 88%), and VUR (21% to 100%).

Clean Intermittent Catheterization

Lapides and colleagues (1972) first introduced the concept of clean intermittent catheterization (CIC) as a method of emptying the bladder in neurologically impaired patients. Since its initial description, this treatment strategy has gradually been employed in neurologically intact individuals with various types of LUTD. In the setting of dysfunctional voiding and in children who postpone micturition, the detrusor muscle stretches and the bladder becomes chronically overdistended. This repeated action over time can lead to underactive bladder with the end result of myogenic failure. In these cases, bladder emptying is often incomplete, resulting in large PVR urine volumes, urinary incontinence, and recurrent UTIs from stasis. CIC is a safe, effective, and well-tolerated treatment strategy to attain continence and reduce the rate of recurrent UTI in children with LUTD (Pohl et al, 2002). It is particularly crucial to discuss the merits of this intervention with sensate patients and their families to maximize adherence.

Pharmacotherapy

Pharmacologic intervention in the treatment of children with LUTD has traditionally encompassed anticholinergic agents and α -adrenergic receptor antagonists (i.e., α -blockers) to enhance bladder filling and emptying, respectively. We will generally initiate one or both of these two medications once all other conservative measures have been exhausted. In some instances we will start α -blockers concomitantly with biofeedback, and this management decision is ultimately left up to the discretion of the provider.

Anticholinergic Agents

Anticholinergics (i.e., antimuscarinics) are the current gold standard in the treatment of patients with symptoms referable to OAB. Muscarinic receptors are found in the human detrusor muscle, and bladder contractions are initiated by stimulation of these receptors with the release of acetylcholine from cholinergic nerves. The main action of anticholinergics is on the M1 and M3 receptor subtypes, which are thought to be responsible for the pathogenesis of detrusor overactivity (Chapple et al, 2002). **These agents act by reducing the frequency and intensity of uninhibited detrusor contractions during the filling phase of the bladder, resulting in an increase in the functional bladder capacity and compliance (Nijman, 2004; Finney et al, 2006).** The clinical efficacy depends

on various factors such as receptor affinity, pharmacokinetics, and the specificity for the bladder.

Oxybutynin was among the first generation of modern antimuscarinic medications available for treating incontinence in children. Five anticholinergic agents are currently approved in the United States for the treatment of OAB (darifenacin, oxybutynin, solifenacin, tolterodine, and trospium), with only two of these (oxybutynin and tolterodine) having formally achieved approval for use in children. Oxybutynin has antimuscarinic, antispasmodic, and analgesic properties. It causes the antispasmodic effect by acting as a calcium channel blocker. The analgesic and antispasmodic properties make the medication particularly attractive; however, these effects occur only with supraphysiologic doses that would render them useless secondary to side effect profile (Chapple, 2000).

The nonselective pattern of activity and penetration of the blood-brain barrier are known to induce systemic and central side effects, respectively. The longer acting extended-release formulation (Oxybutynin XL) is also approved by the U.S. Food and Drug Administration (FDA) for use in children and uses a novel delivery system resulting in absorption in the large intestine (Youdim and Kogan, 2002). This avoids the first-pass metabolism in the liver, leading to a decrease in the active metabolite *N*-desethyloxybutynin, thought to be responsible for many of the adverse effects associated with the use of oxybutynin. **The main side effects include constipation, dry mouth, blurred vision, reduced sweating, flushing, and altered behavior and cognition.** Oxybutynin is lipid soluble and therefore likely to cross the blood-brain barrier and in adults has been reported to interfere with cognition. However, in a non-randomized trial of 25 children, Sommer and colleagues (2005) found that treatment with oxybutynin was not associated with cognitive impairment. Additionally, in a recent study by Veenboer and associates (2013), no significant differences in behavior were found between children with spinal dysraphism with and without long-term use of antimuscarinics.

Other methods of delivery of oxybutynin are intravesical and transdermal. The intravesical method of delivery avoids the first-pass effect and leads to increased amounts of oxybutynin available compared to immediate-release oral oxybutynin. Its use in the non-neurogenic, sensate population is limited, however, because of the need for catheterization. **The transdermal patch is as efficacious as the immediate-release oral form but with nearly half the incidence of dry mouth (Davila et al, 2001).** Local skin erythema and pruritus are side effects unique to this route of administration that can be seen in over one third of patients (Gleason et al, 2014).

α-Adrenergic Receptor Antagonists (α-Blockers)

α-Adrenoreceptors have been demonstrated in the LUT, with a large concentration located at the bladder neck and urethra (Ek, 1978). **α-Adrenergic blockade results in smooth muscle relaxation and decreased bladder outlet resistance.** Limitations of early α-blockers included their side effect profile with hypotension and dizziness. With subsequent development of more “selective” α-blockers in the 1980s that targeted α_{1a}-receptors rather than both α_{1a}- and α_{1b}-adrenergic receptors, these side effects were greatly diminished. Examples of selective α-blockers include alfuzosin, doxazosin, prazosin, silodosin, tamsulosin, and terazosin.

Currently, α-blockers are a mainstay drug used to facilitate bladder emptying in the adult population, particularly in adult males with benign prostatic hyperplasia. Early work on the benefits of α-blockers on pediatric LUTD by Austin and colleagues (1999) pioneered the introduction of α-blockers into the armamentarium of drugs that can be used to treat voiding issues in children. In this pilot report, there was an 82% improvement in the measured parameters of 17 patients treated with α-blocker therapy. In a follow-up of their initial study, the group continued to see improvement in multiple LUTS, daytime incontinence episodes, and PVR measurements in 55 children treated with doxazosin for dysfunctional voiding (Cain et al, 2003).

Please see the Expert Consult website for further details.

α-Blocker treatment selection of children with LUTD is done through a comprehensive treatment program that involves an escalating treatment paradigm (Chase et al, 2010; Thom et al, 2012) or by identifying patients with characteristic uroflow abnormalities (Van Batavia et al, 2010). The uroflow finding of a prolonged “EMG lag time” is associated with bladder neck and internal urethral sphincter discoordination and may be used to select patients for α-blocker therapy (Van Batavia et al, 2011, 2014). The EMG lag time is the time duration after the external sphincter relaxes and the flow of urine. A prolonged lag time of greater than 6 seconds is suggested as a reliable indicator of tailoring LUTD treatment with α-blocker therapy (Van Batavia et al, 2014). Further validation is needed to investigate the reliability and reducibility of these uroflow findings.

Botulinum Toxin

A relatively recent investigational pharmacologic approach in refractory cases of LUTD is botulinum-A toxin (BTX-A). The toxin acts by inhibiting acetylcholine (ACh) release at the presynaptic neuromuscular junction. Inhibited ACh release results in regionally decreased muscle contractility and atrophy at the injection site. The chemical denervation that ensues is a reversible process, and eventually the toxin is inactivated and removed. Clinical effects begin within 5 to 7 days of injection with maximal effects reached within 4 to 6 weeks (Game et al, 2009). The duration of induced paralysis varies depending on the type of muscle treated, with duration of treatment effect lasting between 3 and 12 months (Riccabona et al, 2004).

Clinically, BTX-A injections have been used safely in the treatment of a number of clinical disorders (Maria et al, 2005), including neurogenic LUTD (Game et al, 2009). BTX-A has been subsequently applied to non-neurogenic LUTD, and there are a number of reports of BTX-A used to treat children with OAB and dysfunctional voiding (Steinhardt et al, 1997; Hoebeke et al, 2006; Mokhless et al, 2006; Radojicic et al, 2006; Franco et al, 2007; Petronijevic et al, 2007; Vricella et al, 2014). BTX-A is directly injected into the detrusor muscle (in patients with OAB) or external urinary sphincter (in patients with dysfunctional voiding) under cystoscopic guidance. One of the main drawbacks of this therapeutic modality is the need for re-treatment given the reversible nature of this chemical denervation secondary to synaptic terminal resprouting within 6 months of injection. Fortunately, preliminary studies suggest that repeated BTX-A injections are safe in children and do not induce additional fibrosis in the bladder wall (Pascali et al, 2011).

Neuromodulation

During the last two decades electrical nerve stimulation, also known as neuromodulation, has been applied to the treatment of non-neurogenic LUTD in children (Table 143-1). Several of the reported changes after treatment with neuromodulation include significantly increased bladder capacity, decreased severity of urgency, improved continence, and decreased UTIs (Bower et al, 2001; Hoebeke et al, 2001b; Roth et al, 2008). A significant improvement in urodynamic parameters of bladder compliance, number of involuntary contractions, and bladder volume at first detrusor contraction also have been noted (De Gennaro et al, 2004).

In neuromodulation, electrical stimuli are exerted in a noninvasive manner to alter the existent neural transmission pattern and modulate detrusor activity. The putative mechanism involves acting centrally by rebalancing excitatory and inhibitory information and returning the neural drive toward a more neutral status. A number of modalities have been studied in children, including sacral neuromodulation, pudendal nerve stimulation, and tibial nerve stimulation. Although preliminary results have been promising, electrical nerve stimulation's role in children with non-neurologic LUTD nevertheless remains controversial because of the lack of controlled trials and largely obscure mechanism of action.

With transcutaneous electrical nerve stimulation (TENS) superficial electrodes are placed on each side of the S3 and S2 spinal cord

Kramer and colleagues (2005) conducted the first randomized, placebo-controlled study of selective α -blocker therapy in children with dysfunctional voiding. Thirty-eight children were randomized to either placebo or 0.5 mg of doxazosin. Unlike in previous studies, they found no significant difference in the PVR and uroflow measurements between the treatment groups. There was a trend toward a significant improvement in urinary incontinence (4 vs. 14 incontinent episodes per week from a median baseline of 18 weekly episodes) and the DVSS parental survey in the α -blocker group compared to the placebo group. There was a significant difference in parental satisfaction, with a higher parental satisfaction in the children treated with α -blockade.

Vanderbrink and colleagues (2009) reported an observational study of 23 children with bladder neck dysfunction who were treated for an average of 10 months with tamsulosin. The number of incontinent episodes decreased from over 5.5 to less than 1 episode on average per day. In addition, increases in Qavg and Qmax and a reduction in PVR urine and abnormal uroflow patterns were observed during therapy. The safety profile for α -blockade in this pediatric population also was assessed, and the results were consistent with those in other reports using selective α -blockers in children. Although orthostatic hypotension was not formally evaluated, the authors did not find any significant alterations of blood pressure measurements and there were no reports of any symptomatology suggestive of hypotension.

TABLE 143-1 Studies Evaluating Neuromodulation in Treatment of Children with Lower Urinary Tract Dysfunction

REFERENCE	ES TYPE	LUTD	NO. PTS	TREATMENT SCHEME	FREQUENCY/AMPLITUDE	TREATMENT PERIOD	FOLLOW-UP (mo)	OUTCOME (%)
Hoebeke et al, 2001b	TENS	OAB	41	S3: 2 hr/day	2 Hz/not stated	6 mo	12	56 cured, 20 improved

segments. In general, therapy consists of 20-minute sessions three times per week. Percutaneous tibial nerve stimulation (PTNS) is performed with a 34-gauge stainless steel needle inserted approximately 5 cm cephalad to the medial malleolus and a grounding pad placed just posterior to the medial malleolus. Proper needle placement in children is confirmed by observing ipsilateral plantar and/or toe flexion or fanning. Although the purported mechanism of action differs somewhat, neuromodulation by PTNS is based on the traditional Chinese practice using the Sanyinjiao acupuncture point, which overlies the posterior tibial nerve (van Balken et al, 2004). The posterior tibial nerve is a mixed sensory and motor nerve originating from the L4 to S3 spinal roots that also contributes to sensory and motor control of the bladder, urinary sphincter, and pelvic floor musculature. Therapy has been invariably applied once weekly, usually for 30-minute outpatient treatment sessions.

Since its initial description, a significant number of reports have been generated on sacral nerve root stimulation via implantable electrodes. In the last decade sacral nerve modulation (SNM) has gained widespread recognition in adults and was approved by the FDA for use in urology for urinary urgency/frequency, urge incontinence, pelvic floor dysfunction, and nonobstructive urinary retention. Despite off-label use, a number of groups have reported on their experience with SNM in children with non-neurogenic LUTD (Tanagho, 1992; Humphreys et al, 2006; Roth et al, 2008; McGee et al, 2009; Stephany et al, 2013).

Before sacral implantation can be performed, percutaneous transforaminal access to the S3 spinal nerve must be achieved. Once the correct responses are obtained, the quadripolar tined lead of the neurostimulator device can be implanted. This lead can then be connected to an external neurostimulator device via a tunneled subcutaneous extender for programming and trial assessments. If this is successful, the patient undergoes a second procedure to implant the permanent neurostimulator device into a subadipose pocket in the upper gluteal region. Complications commonly cited with implantable SNM devices are device and/or wound infection, electrode migration, loss of effect, and lead fracture. Revision rates range between 7% and 18%, secondary to lead migration, faulty connection, and infection.

Special Conditions of Lower Urinary Tract Dysfunction and Their Treatment

Giggle Incontinence (Enuresis Risoria)

Enuresis risoria is an uncommon form of daytime incontinence classically seen in school-aged females. Typically, moderate-to-large amounts of urinary leakage are triggered by laughing alone. The accepted theory is that of a central nervous system (CNS) inactivation (i.e., cataplexy) in association with laughter resulting in urinary incontinence (Sher and Reinberg, 1996). It should be emphasized that the incontinence episodes are invariably significant and often the entire bladder volume is drained. Daytime urinary incontinence in conjunction with laughter is also seen in children with OAB and is more common than true giggle incontinence. It is a diagnosis of exclusion and is usually established on history and is supplemented by the absence of other voiding symptoms and normal investigations. Giggle incontinence has a significant adverse effect on the social life, and this is often why medical assistance is sought. Currently, available treatment strategies include biofeedback or methylphenidate (Berry et al, 2009; Richardson and Palmer, 2009).

Pollakiuria (Extraordinary Daytime Urinary Frequency)

This is a disorder characterized by a very high daytime frequency of micturition (sometimes as high as 50 times per day). A key aspect of this syndrome, which differentiates it from OAB and often can clinch the diagnosis, is that the symptoms are limited only to the daytime. It is seen in early childhood (4 to 6 years of age) in both genders and associated with a history of recent death or life-threatening event in the family. Usually, it runs a benign, self-

KEY POINTS: MANAGEMENT OF DAYTIME URINARY INCONTINENCE AND BLADDER DYSFUNCTION

- The management of a child or adolescent with LUTD is primarily directed at improving symptoms (e.g., urinary and/or fecal incontinence, recurrent UTIs) and protecting the upper urinary tract from permanent damage.
- In general, a stepwise approach is used with an algorithm that progresses from least to most invasive with conservative measures (e.g., treatment of constipation, behavioral modification) exhausted before initiating medications, physical therapy, biofeedback, neuromodulation, or surgical intervention.
- In one large study, relief of constipation alone resulted in the disappearance of daytime urinary incontinence in 89% and enuresis in 63% of patients studied (Loening-Baucke, 1997).
- Anticholinergics are the current gold standard in the treatment of patients with symptoms referable to OAB. These agents act by reducing the frequency and intensity of uninhibited detrusor contractions during the filling phase of the bladder, resulting in an increase in the functional bladder capacity and compliance. The main side effects include constipation, dry mouth, blurred vision, reduced sweating, flushing, and altered behavior and cognition.
- α -Adrenergic blockade results in smooth muscle relaxation and decreased bladder outlet resistance to facilitate bladder emptying.
- In neuromodulation, electrical stimuli are exerted in a non-invasive manner to alter the existent neural transmission pattern and modulate detrusor activity. The putative mechanism involves acting centrally by rebalancing excitatory and inhibitory information and returning the neural drive toward a more neutral status. A number of modalities have been studied in children, including SNM, pudendal nerve stimulation, and tibial nerve stimulation.

limited course over a period of approximately 6 months (Bergmann et al, 2009). No specific treatment, apart from reassurance, is necessary. Children presenting with frequency, however, merit clinical investigation to exclude other pathologic causes.

Underactive Bladder

As the name suggests, underactive bladder describes a child who is required to raise intra-abdominal pressure to initiate, maintain, and complete voiding. Once a functional or anatomic cause for BOO has been ruled out, there are two main approaches to this entity. The first is with timed voiding and double voiding to more efficiently empty the bladder and lower the ultimate PVR volume of urine. If this treatment strategy fails to achieve the desired effect, we often recommend CIC with frequency dependent on symptom severity. Obviously, this requires appropriate counseling and thoughtful guidance of both patient and caregiver, especially in the child who is neurologically intact.

Vaginal Reflux (Vaginal Entrapment and Vaginal Voiding)

Vaginal reflux is characterized by incontinence after normal voiding in the absence of other LUTS. It is commonly seen in prepubertal girls, and the typical history is that of wetting of undergarments approximately 10 to 15 minutes after a normal void. It often can be associated with labial adhesions as a result of chronic irritation and inflammation from skin exposure to relatively caustic urine. Reassurance and postural modification to ensure complete vaginal emptying is the only treatment required.

ENURESIS

Over the last several decades, much has changed in our understanding of enuresis. Previous notions of voluntary control have been replaced by an appreciation of genetic and pathophysiologic mechanisms. What is known with certainty is that enuresis is a common medical condition in children (Shreeram et al, 2009). It affects millions of children throughout the world and is associated with significant negative impacts on self-esteem and health-related quality of life (Wolfe-Christensen et al, 2013).

Terminology and Background

The term *enuresis* is synonymous with *nocturnal enuresis* and is defined as discrete episodes of urinary incontinence during sleep in children over 5 years of age in the absence of congenital or acquired neurologic disorders. The term *diurnal enuresis* has been eliminated completely. The child who wets during the day and night can be said to have daytime urinary incontinence and enuresis or non-monosymptomatic enuresis.

Enuresis is categorized as monosymptomatic (MSE) or non-monosymptomatic (NMSE). MSE is defined as enuresis in children without any other LUTS and without a history of bladder dysfunction. MSE is further subdivided into *primary* and *secondary* forms. Children who have *never* achieved a satisfactory period of nighttime dryness (~80% of enuretic children fit this definition) have primary MSE (Friman and Warzack, 1990). Children who develop enuresis after a dry period of at least 6 months are said to have secondary enuresis (von Gontard and Nevés, 2006). Secondary enuresis often is ascribed to an unusually stressful event (e.g., parental divorce, birth of a sibling, sexual abuse) or an organic (e.g., UTI, diabetes, obstructive sleep apnea, neurogenic bladder) or psychological cause (e.g., ADHD or conduct disorder) at a time of vulnerability in a child's life. These children are more likely to have NMSE (see next) and respond less well to treatment. The exact cause of secondary MSE, however, remains largely unknown. The clinical presentations of children with primary and secondary MSE are otherwise similar, which suggests a common pathogenesis (Robson et al, 2005). Moreover, large family studies have demonstrated that secondary MSE is usually no different etiologically from primary MSE, with undue emphasis on their difference being unwarranted (Schaumburg et al, 2008).

Enuresis with any daytime LUTS is defined as NMSE (Franco et al, 2013). Daytime LUTS suggesting NMSE include daytime incontinence (not obligatory), frequency, genital or LUT pain, and holding maneuvers (i.e., strategies to postpone voiding). A careful history is often required to elicit these symptoms, which usually indicate either OAB (i.e., a storage issue) such as urgency or dysfunctional voiding (i.e., emptying problems) such as hesitancy, straining, weak stream, intermittency or a feeling of incomplete emptying.

The pathogenesis, evaluation, and treatment of MSE and NMSE overlap considerably (Nevés et al, 2010). Approximately 15% to 30% of enuretic children experience daytime LUTS; however, these reported numbers are likely grossly underestimated (Järvelin et al, 1988; Gumus et al, 1999). In fact, most experts in the field would estimate the proportion of children with enuresis that are truly monosymptomatic to represent fewer than half of all bedwetting children (Franco et al, 2013).

Our initial approach to NMSE is nearly identical to our approach for children with LUTD. Obviously one begins with a thorough history and physical examination, along with the appropriate laboratory and imaging studies. In terms of NMSE therapy, we also begin by identification and treatment of constipation. As we have previously seen, effective treatment of bowel problems can lead to the spontaneous remission of daytime incontinence (Loening-Baucke, 1997). We also will treat the underlying LUTD symptoms first, because effective treatment of OAB (or dysfunctional voiding) can lead to cessation of the enuresis entirely (Franco et al, 2013). If comorbid behavioral disorders are present, these should be addressed by an appropriate provider. If enuresis persists after the

Figure 143-9. Prevalence rate of enuresis from childhood through young adulthood. (From Austin PF, Nevés T. Evaluation and management of enuresis. AUA Update Series, Vol. XXI, 2012.)

previously mentioned interventions, standard treatment for MSE can follow. The remaining section of this chapter will focus specifically on MSE and its epidemiology, cause, evaluation, and treatment strategies.

Epidemiology and Natural History

Enuresis is a common problem, with an estimated 7 million children in the United States alone with this condition. According to a recent large longitudinal study in the United Kingdom, at least 20% of children in the first grade occasionally wet the bed and 4% wet the bed two or more times per week (Butler and Heron, 2008). Prevalence varies with age, suggesting an immaturity of the LUT and nervous system (Fig. 143-9). In a study of almost 11,000 children in the United States, the prevalence of enuresis in boys at 7 and 10 years of age was 9% and 7%, respectively, and in girls at those ages, 6% and 3%, respectively (Byrd et al, 1996). It is currently generally accepted that in the West approximately 15% of children will have some degree of nighttime wetting at 5 years of age, with a spontaneous resolution rate of approximately 15% per year (Forsythe and Redmond, 1974). Consequently, at 15 years of age only 1% to 2% of teenagers will still wet the bed (Klackenberg, 1981). It has also been shown that the longer the enuresis persists, the lower the probability is that it will resolve spontaneously (Forsythe and Redmond, 1974; Bakker et al, 2002).

Enuresis seems to be more common in boys than in girls, with most reports revealing a 2:1 ratio. Although this finding has been disputed by other groups, it is well accepted that by adolescence the prevalence in both males and females reaches equipoise (Yeung et al, 2004b).

Enuresis is also known to be common in children with comorbid behavioral issues such as ADHD, oppositional defiant disorder, conduct disorder, anxiety, and depression (Baeyens et al, 2004; von Gontard et al, 2011). It is estimated that 20% to 30% of children with enuresis have comorbid clinical behavioral disorders that fulfill the criteria for the DSM-V psychiatric disorders and may subsequently have a negative impact on compliance and ultimate outcome if left untreated (von Gontard et al, 2011).

Genetics

Enuresis has a complex and multifactorial pathophysiology with a strong genetic underpinning (von Gontard et al, 1998a; Schaumburg et al, 2008). When one or both parents have a history of prolonged nighttime wetting, approximately 43% and 77%, respectively, of the offspring are affected (Bakwin, 1973). When neither parent has a history of nocturnal enuresis, only 15% of offspring are affected (Bakwin, 1973). Moreover, the concordance among

monozygotic twins is almost twice that among dizygotic twins (68% vs. 36%) (Bakwin, 1971). Linkage of enuresis to markers on chromosomes 12, 13, and 22 has been reported, with autosomal dominant inheritance and high penetrance suggested; however, a major gene locus has yet to be identified (Eiberg et al, 1995, Eiberg 1998; Arnell et al, 1997). Family and twin studies suggest locus heterogeneity and poor phenotype-genotype correlation (von Gontard et al, 2011b). The identification of these genes certainly lifts the burden of guilt from children who have enuresis and helps to dispel the theory that enuresis is behavioral in origin and completely under their control.

Pathophysiology

It is generally accepted that enuresis stems from a maturational delay in the ultimate development of bladder control (Järvelin, 1989; Light, 1998). This contention is rooted in the fact that most children eventually attain nocturnal dryness regardless of what intervention is used and even if enuresis is left untreated. The hypothesis that there is a difference in the CNS maturation in children with primary enuresis compared with controls is supported by neurophysiologic data (Isacan et al, 2002). Many children who have enuresis are noted to have progressive maturation of bladder stability in conjunction with electroencephalography (EEG) findings that suggest increased CNS recognition of bladder fullness and the ultimate ability to suppress the onset of bladder contraction (Watanabe and Azuma, 1989). This would further lend credence to the premise that delayed maturation of the bladder control plays a role in MSE.

Put very simply, the three organ systems implicated in the pathogenesis of enuresis include the bladder (i.e., a reduced nocturnal bladder capacity) (Yeung et al, 2004a), the kidney (i.e., nocturnal polyuria) (Nørgaard et al, 1989a; Vande Walle et al, 2007), and the brain (i.e., a disorder affecting arousal from sleep) (Watanabe and Azuma, 1989; Isacan et al, 2002). Enuresis is logically thought to result from a disruption or maturational lag in one or more of these critical domains (Fig. 143-10).

Bladder Overactivity and Reduced Nocturnal Bladder Capacity

There seems to be a subset of children with primary MSE who have nocturnal bladder overactivity regardless of amount of urine production (Yeung et al, 1999). Yeung and associates found that nearly half of treatment failures with standard therapy (i.e., desmopressin or moisture alarm) had normal daytime bladder function but marked detrusor overactivity during sleep that resulted in enuresis. Almost none of these children had nocturnal polyuria.

When urodynamic studies are performed during sleep, the only difference between children with and without MSE is the increased rate of bladder contractions that occur in association with the enuretic episode (Nørgaard et al, 1989b). In addition, urodynamic

studies during sleep demonstrate a relationship between nocturnal enuresis and pelvic floor activity. When pelvic floor activity increased in association with detrusor contractions, wetting was usually avoided, and patients often would awaken subsequently to void. In contrast, when pelvic floor activity did not increase, the detrusor contraction usually was associated with a wetting episode (Nørgaard et al, 1989b).

Please see the Expert Consult website for further details.

Nocturnal Polyuria

Increased nighttime urine output appears to play an important role in nocturnal enuresis (Nevéus et al, 2010). In children and adolescents without enuresis, the diurnal pattern of urine production results in a relative reduction in nocturnal diuresis to approximately 50% of daytime levels (Rittig et al, 1995, 2010). The prevailing mechanism for how this occurs is thought to result from a nocturnal circadian peak of antidiuretic hormone (ADH) release from the posterior pituitary gland that regulates free water excretion. Other purported mechanisms for increased nocturnal urine production may include increased fluid intake before bedtime (Robson, 2001), a blunted response to ADH, increased evening dietary solute load with high nocturnal urine osmolality (Dehoorne et al, 2006), abnormal renal sodium handling (related to release of angiotensin II, aldosterone, and natriuretic peptide), abnormal circadian rhythm of glomerular filtration rate (De Guchteneere et al, 2007), abnormal sodium and calcium excretion (Raes et al, 2006), and obstructive sleep apnea/hypoventilation (Su et al, 2011).

Regardless of the mechanism, urine production that normally decreases at night secondary to these circadian systems fails to do so and will subsequently result in nocturnal polyuria, which can exceed the functional capacity of the bladder and result in an enuretic episode. Proof of this concept was demonstrated by Rasmussen and colleagues (1996), who were able to actually induce enuresis in normal healthy children by increasing nocturnal urine output. Despite this seemingly simple causal relationship, however, it is clear that nocturnal polyuria and ADH responsiveness are highly complex phenomena, because not all children with enuresis have nocturnal polyuria and, in those who do, nocturnal ADH may be normal (Steffens et al, 1993). In fact, it has been observed that the urine osmolality of children with and without MSE is similar and that early morning osmolality tends to increase with age (Kawauchi et al, 1996). This suggests that the ADH secretion response may be a maturational one and lend further support to the maturation hypothesis.

Arousal and Sleep

Regardless of whether the child has detrusor overactivity and/or nocturnal polyuria, neither observation explains why a child with enuresis is unable to awaken from sleep to void before a wetting episode. Given that both bladder distention and detrusor contractions are robust arousal stimuli (Koyama et al, 1998), it is curious that an enuretic child will not wake up during the night to the sensation of a full or contracting bladder. Parents invariably describe their children with enuresis as excessively deep sleepers (Wille, 1994; Nevéus et al, 1999a). This situation is often experienced by family members of patients exposed to alarm therapy as parents awaken from sleep while their enuretic child will sleep through the alarm. Nevéus and colleagues (1999a) obtained questionnaire data from 1413 schoolchildren between the ages of 6 and 10 years and noted that enuresis was associated with subjectively high threshold arousal and significant confusion on awakening from sleep. Wolfish and coworkers (1997) performed a laboratory study of 33 boys aged 7 to 12 years (15 with enuresis and 18 age-matched controls) and found that attempts at arousal were more often successful in control subjects than in boys with enuresis (40% vs. 9%, respectively).

A subjectively deep sleep, however, is not the same as an objectively deep sleep, as measured by EEG. Freitag and associates (2006) studied brainstem evoked potentials in 37 children with MSE and compared these children to 40 age-matched controls. They found

Figure 143-10. Organ system involvement in pathogenesis of enuresis.

Children with enuresis (even those without daytime symptoms) have been noted to have a smaller bladder capacity than age-matched children controls (Starfield, 1967). The reduced bladder capacity appears to be functional rather than anatomic. This was illustrated by a study in which bladder capacity was measured in the awake state as well as under general anesthesia in children with enuresis and compared with functional bladder capacity among controls (Troup et al, 1971). Compared with control children, the average volume of urine voided by enuretic children in the awake state was reduced. However, when volumes were measured during general anesthesia, enuretic children had similar mean bladder volumes to awake controls. In a somewhat contradictory study, Kawauchi and colleagues (2003) found that the maximal endurable bladder capacity during the daytime was similar between children with enuresis and controls. However, among children with enuresis, the maximal voided volume during the night (measured using a diaper and enuresis alarm) was significantly smaller than the maximal daytime bladder capacity. They concluded that inability to hold urine during sleep may be an important factor in MSE. A number of trials have noted functional bladder capacity to be a strong predictor of response to desmopressin in MSE (Rushton et al, 1996; Eller et al, 1998). As a result, a refractory response to desmopressin may suggest either unrecognized nocturnal OAB or that the decreased nocturnal urine production elicited by desmopressin continues to overwhelm a functionally undersized bladder. Whether this situation is a result of reduced nocturnal functional bladder capacity or nocturnal detrusor overactivity, however, may not be critical because the treatment strategy employed would largely be the same (i.e., anticholinergic medications).

that interpeak latencies of the brainstem evoked potentials were increased in children with MSE, suggesting a maturational defect of the brainstem to account for this finding. Other sleep studies, however, show that sleep patterns among children with and without enuresis are similar (Ritvo et al, 1969; Bader et al, 2002). These studies indicate that enuretic episodes may occur at random throughout the night, but primarily during nonrapid eye movement (non-REM) sleep (Nevéus et al, 1999b) and when the bladder is at a volume equivalent to the maximal daytime functional capacity (Mikkelsen et al, 1980; Nørgaard et al, 1989b). A study of 35 children with therapy-resistant MSE in Hong Kong demonstrated that although appearing to be heavy sleepers, these children had, in fact, more overall light sleep (stage I/II non-REM) with sleep fragmentation, rather than deep sleep (stage III/IV non-REM). The cerebral cortex received afferent input of sleep OAB with frequent cortical arousals that failed to wake the children, which was presumed to be a paradoxical elevation in the conscious awakening threshold. OAB-associated cortical arousals may cause a shift from deep to light sleep but not to complete awakening, perhaps because of long-term overstimulation of the sleep arousal center by signals from the bladder. In summary, these studies suggest that children who wet the bed sleep normally (i.e., the distribution and proportion of the various stages of sleep are within normal limits) but are unable to awaken in response to nocturnal detrusor contractions or bladder fullness.

Evaluation

The basic evaluation of the child with MSE includes **history, physical examination, and urinalysis. The history, including a voiding diary, is the mainstay of the evaluation** (Robson, 2009; Nevéus et al, 2010). As previously discussed, the voiding diary is an objective means of documenting the voiding pattern (see section on *Bladder and Bowel Diaries*). This is especially useful when the history is unclear. A voiding diary kept by the parents should help assess the times at which a child voids; the relationship between voiding and common events such as meals, breaks at school, and play activities; the occurrence of urgency or incontinence; and voided volume. **The principal objective of the evaluation is to rule out BBD or enuresis as a manifestation of an underlying medical disease (e.g., posterior urethral valves, spinal dysraphism, diabetes mellitus) and to identify that the enuresis is truly monosymptomatic.** If BBD is present, it should be treated as described previously before initiating therapy for MSE (Franco et al, 2013).

Once MSE is confirmed, it is often helpful to characterize the enuresis further, such as frequency and volume. Distinguishing between primary and secondary MSE should be attempted, mainly for prognostic purposes because treatment is generally the same. One important point to ask about is the presence of nocturia; this would suggest that the child is not extremely difficult to arouse from sleep. The social history is also particularly germane because somatic and psychological comorbid conditions are more common in children who were previously dry than in those with primary MSE (Robson et al, 2005). A family history of enuresis is often helpful in establishing a genetic pattern. Interventions the family has already tried also should be determined.

The physical examination should be focused and is similar in scope to that described in the prior section on LUTD. Briefly, examination should include palpation of the abdomen to screen for constipation, examination of the lower spine for cutaneous stigmata of spinal dysraphism, examination of the genitalia to screen for meatal stenosis, introital erythema or damp/wet underwear, assessment of the sacral reflex arc, and evaluation of the motor strength, tone, reflexes, and sensation in the legs for evidence of a neurogenic bladder.

In terms of laboratory testing, a simple urinalysis should be performed to detect any possible glucosuria, proteinuria, hematuria, pyuria, and/or bacteriuria. Neither radiologic imaging nor urodynamics has a role in the evaluation of MSE. If based on history and physical examination the patient is suspected to have NMSE, we would recommend evaluation following the previously

described protocol for children with LUTD (i.e., pelvic ultrasound and uroflowmetry).

Treatment

Conventional therapies for enuresis include behavioral modification, the enuresis “moisture” alarm, and pharmacologic therapy (e.g., desmopressin, anticholinergics, imipramine). The evidence for the efficacy of much of the care that we provide to children with enuresis is weak (Nevéus et al, 2010). Given the self-limiting nature of enuresis, one treatment option is to observe and allow the natural history to follow its predetermined course. However, enuresis that occurs as infrequently as once per month is associated with reduced self-esteem and treatment has been reported to improve self-worth, regardless of the type or the success of therapy (Hägglöf et al, 1998; Longstaffe et al, 2000).

The decision about when to start treatment generally should be guided by the degree of concern and motivation on the part of the child rather than the parents. For the child, nocturnal enuresis usually becomes significant when it interferes with his or her ability to socialize with peers (e.g., sleepovers, summer camps) (Jalkut et al, 2001). **It is important to determine whether the child is mature enough to assume responsibility for treatment.** Treatment probably should be delayed if it seems that the parents are more interested in treatment than the child and the child is unwilling or unable to assume some responsibility for the treatment program. The child must be highly motivated to participate in a treatment program that may take months to achieve successful results. Although general advice should be given to all bedwetting children, active treatment should usually not be started before 6 years of age (Nevéus et al, 2010). However, age should not be the only criterion for initiation of active treatment.

Behavioral Therapy

Data from randomized trials on the efficacy of behavioral therapy are lacking (Pennesi et al, 2004; Caldwell et al, 2013), but clinical experience (i.e., level 4 evidence) suggests that this approach is beneficial (Nevéus et al, 2010). Likewise, although the influence of the clinician's behavior has not been formally studied, clinical experience suggests that the ability to establish a rapport with the child and to engender and sustain motivation is important for successful behavioral therapy. **The fundamental goal of behavioral therapy is much like the treatment of daytime urinary incontinence and centers around the practice of good bladder and bowel habits.**

Children should attempt to void regularly during the day and just before going to bed for a total of six to seven times daily. High-sugar and caffeine-based drinks should be avoided, particularly in the evening hours. Daily fluid intake should be concentrated in the morning and early afternoon, and both fluid and solute intake should be minimized during the evening. Isolated nighttime fluid restriction, without compensatory increase in daytime fluid consumption, may prevent the child from meeting his or her daily fluid requirement and is usually unsuccessful.

In practice, compliance improves when parents and children understand normal bladder function and the pathogenesis of enuresis. **Children should be reassured that enuresis is not their fault, and children should not be punished for bedwetting, because this practice is often counterproductive** (van Londen et al, 1993). An individualized program with a series of realistic goals between appointments and monthly follow-up to sustain motivation improves the outcome (Glazener and Evans, 2004). A personalized calendar for recording daytime incontinence and enuresis episodes and the frequency and timing of bowel movements aids the family and child to follow their progress.

When initiating active treatment for primary MSE, there is level 1 evidence to support the use of the enuresis alarm (Glazener et al, 2005), **desmopressin** (Glazener and Evans, 2009), **anticholinergics** (Austin et al, 2008), and **tricyclic antidepressants (e.g., imipramine)** (Glazener and Evans, 2000), either alone or in combination. Generally, in addition to behavioral therapy, the two

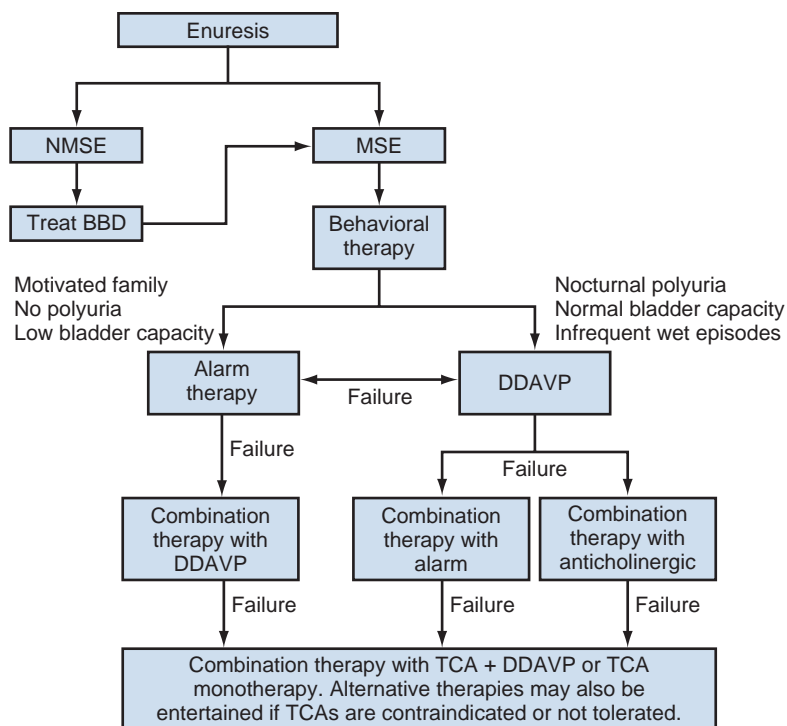

Figure 143-11. Algorithm of the evaluation and treatment of a pediatric patient with enuresis. BBD, bowel-bladder dysfunction; DDAVP, 1-deamino-8-D-arginine vasopressin (desmopressin); MSE, monosymptomatic enuresis; NMSE, nonmonosymptomatic enuresis; TCA, tricyclic antidepressant.

contemporary first-line therapies for MSE include the enuresis alarm and desmopressin. They are both valid treatment options, but patient, caregiver, and disease-related parameters exist that may aid in offering prognostic information in terms of which therapeutic modality should be first entertained (Fig. 143-11). The enuresis alarm seems best fit for motivated families and for children without polyuria but with low voided volume (Nevéus et al, 2010). Desmopressin seems best suited for children with nocturnal polyuria and normal bladder reservoir function (Hunsballe et al, 1998), those with infrequent wet episodes, and for families in whom alarm treatment has failed or who have refused alarm treatment (Nevéus et al, 2010). Children in whom one first-line treatment has failed should be offered the other, and for those in whom both have failed, second- and third-line treatments can be tried, either alone or in combination (e.g., desmopressin plus oxybutynin).

Enuresis Alarm

Alarm training has been shown to be the most effective long-term therapeutic modality in the treatment of MSE (Glazener et al, 2005). Alarms have been used since the 1930s and represent classic pavlovian conditioning techniques, but exactly how the alarm works remains somewhat of a mystery because, strictly speaking, classical conditioning mechanisms should not be functional during sleep. Proposed mechanisms include suppression of bladder emptying during sleep, increasing nocturnal bladder volume (Hansen and Jørgensen, 1997), and waking to void by signaling when they urinate. Interestingly, most children who become dry with the use of the enuresis alarm actually sleep through the night and do not necessarily wake to void. The response is more gradual and sustained than for desmopressin, with approximately two thirds of children becoming dry during active treatment and nearly half remaining dry after treatment completion (Glazener et al, 2005). Enuresis alarms are activated when a sensor, placed in the undergarments or on a bed pad, detects moisture, with both types demon-

strated to be equally effective (Butler and Robinson, 2002). The arousal device is usually an auditory alarm and/or a vibrating belt.

The family should be instructed that the child is in charge of the alarm. After the alarm goes off, only the child should turn off the alarm, get up, and finish voiding in the toilet. We often remind parents that at the initiation of therapy, the child may fail to awaken and that parents should wake the child when the alarm sounds. The child being fully awake and cognizant of what is happening is critical to the success of alarm therapy. The child should then return to the bedroom, change the bedding and underwear, replace the sensor, and reset the alarm before returning to sleep. A diary should be kept of wet and dry nights, with positive reinforcement given for dry nights as well as successful completion of the sequence of events. Approximately 30% of patients discontinue enuresis alarms for various reasons, including skin irritation, disturbance of other family members, and/or failure to wake the child (Schmitt, 1997). Adverse effects of alarms include alarm failure, false alarms, disruption of the lives of other family members, and lack of adherence because of difficulty using the alarm (Glazener et al, 2005).

Alarm treatment should be continued until the child has had a minimum of 14 consecutive dry nights (Nevéus et al, 2010). Children who do not continue to improve after 6 weeks of alarm training are unlikely to become completely dry with this technique (Taylor and Turner, 1975), and alternative interventions may be warranted. Therapy with the alarm can be reinitiated for relapse (more than two wet nights in 2 weeks). Children who relapse after discontinuation of the alarm usually can achieve a rapid secondary response because of preconditioning as a result of the first treatment program (Tuncel et al, 2008). During this refractory treatment period, the chance of long-term cure can be increased by a technique called *overlearning* (Morgan, 1978). In overlearning, additional fluids are given at bedtime while alarm training is continued after dryness has been achieved (Young and Morgan, 1972). In alarm training without overlearning, the child trains to inhibit urination without necessarily learning to wake to void. A systematic review indicated that overlearning trains the child to wake in

response to the sense of a full bladder and reduces relapse when alarm treatment is stopped (Glazener et al, 2005).

Pharmacotherapy

Desmopressin

Desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]) is a synthetic analogue of ADH released by the posterior pituitary gland that reduces urine production by increasing water reabsorption by the collecting tubules. DDAVP has been used to treat enuresis for the past 40 years. Desmopressin is fairly easy to administer and its clinical effects appear immediately, with a serum half-life of approximately 2 to 3 hours when taken in oral form (the duration of pharmacodynamic action approximates the average duration of sleep for a child in the age range for elementary school). It is available in the United States in oral (crushable) tablets and in sublingual and intranasal spray formulations. The main safety issue is the risk for water intoxication with resultant hyponatremic seizures should the drug be taken with excessive fluids. This risk seems to be somewhat higher with the intranasal form, which has a prolonged half-life, and thus use of the spray is discouraged (Robson et al, 2007). Treatment should be interrupted during episodes of fluid and/or electrolyte imbalance (e.g., fevers, vomiting or diarrhea, vigorous exercise, or other conditions associated with increased water consumption).

The usual starting dose is 0.2 mg orally 1 hour before bedtime, and the drug can be titrated up incrementally by 0.2 mg to a maximum dose of 0.6 mg at bedtime. Children are instructed to void directly before going to bed. Fluid intake is reduced to a maximum of one 8-oz glass at the time of ingestion, with absolutely no more fluids until morning, decreasing the risk for significant hyponatremia to virtually zero (Glazener and Evans, 2009).

Desmopressin is most efficient in children with nocturnal polyuria (defined by the ICCS as nocturnal urine production >130% of expected bladder capacity for age) and normal bladder reservoir function (maximum voided volume >70% of expected bladder capacity for age) (Rushton et al, 1996; Hunsballe et al, 1998; Austin et al, 2014). There is a wide range of efficacy among studies, most likely because of heterogeneous patient populations (MSE vs. NMSE), differences in concomitant behavioral therapy recommendations, and differences in the dosage or formulation of DDAVP, without taking into account nocturnal urine volume. Overall, approximately 30% of patients achieve total dryness and another 40% exhibit a significant decrease in nighttime wetting (Nevéus et al, 2010). However, the relapse rate after discontinuation is high (60% to 70%) (Wille, 1986). In a systematic review of 47 randomized trials (3448 children), researchers noted that compared with placebo, children treated with desmopressin were more likely to become dry and had a reduction in bedwetting by 1.34 nights per week (Glazener and Evans, 2009). In contrast to the enuresis alarm, however, treatment effects were not sustained after discontinuation of therapy, with a relapse rate of 65% versus 46% with DDAVP versus the alarm, respectively (Glazener and Evans, 2009).

The response to desmopressin should be assessed within 2 weeks (Schmitt, 1997). Treatment should be continued if there is a positive response (e.g., smaller wet patches, fewer wetting episodes). If enuresis improves or remits with desmopressin, the family and child can determine whether to use it every night or just for special occasions (e.g., sleepovers, summer camp). When DDAVP is administered daily, we generally give patients regular scheduled drug holidays of approximately 1 week every 3 to 6 months to assess whether the medication is still needed.

Tricyclic Antidepressants

Tricyclic antidepressants (TCAs) have been demonstrated to decrease the amount of time spent in rapid eye movement (REM) sleep, stimulate ADH secretion, and relax the detrusor muscle via weak anticholinergic properties. Its antienuretic effect has been theorized

to be less likely because of its action at the kidney or bladder level and more likely a result of noradrenergic stimulation at the brainstem, specifically the locus coeruleus (Gepertz and Nevéus, 2004). Given the efficacy and safety of enuresis alarms and DDAVP, TCAs (e.g., imipramine, amitriptyline, and desipramine) are considered a third-line treatment for therapy-resistant MSE (Nevéus et al, 2010).

Level 1 evidence demonstrates that compared to placebo, TCAs are more effective at reducing the number of wet nights and at achieving 14 consecutive dry nights (i.e., cure) but essentially become ineffective once treatment is discontinued.

Please see the Expert Consult website for further details.

Although other TCAs are effective, imipramine is used most often in the treatment of enuresis. Imipramine is available in 10-, 25-, and 50-mg tablets. The initial dose is 10 to 25 mg 1 hour before bedtime; it may be increased by 25 mg if there is no response after 1 week (Schmitt, 1997). On average, the bedtime dose is 25 mg for children 5 to 8 years of age and 50 mg for older children. The dose should not exceed 50 mg in children between 6 and 12 years of age and 75 mg in children older than 12 years of age (Glazener and Evans, 2000).

The response to imipramine should be assessed after 1 month. If there is no improvement after 3 months, it should be discontinued as a gradual taper (as is done with other TCAs). As is the case with other pharmacotherapy for enuresis, we give patients a drug holiday every 3 to 6 months, gradually tapering the dose over a 2-week period (Gepertz and Nevéus, 2004).

Adverse effects of TCA therapy are relatively uncommon. Approximately 5% of children treated with TCAs develop neurologic symptoms, including nervousness, personality change, and disordered sleep. TCAs (as with other antidepressants) are required by the FDA to carry a black box warning regarding the possibility of increased suicidality, particularly in individuals with preexisting depressive symptoms. The most serious adverse effects of TCAs involve the cardiovascular system: cardiac conduction disturbances and myocardial depression, particularly in cases of overdose (Swanson et al, 1997). Before initiation of therapy with a TCA, a thorough cardiac history (e.g., palpitations, syncope) and family cardiac history (e.g., arrhythmias, sudden cardiac death) should be obtained with a baseline electrocardiogram to rule out a prolonged QT interval if history or physical examination raises suspicion.

Anticholinergics

Monotherapy with anticholinergic drugs, such as oxybutynin or tolterodine, has been demonstrated not to be effective as a first line of treatment for MSE (Lovering et al, 1988; Persson-Jünemann et al, 1993). Although evidence of efficacy from randomized trials is lacking, uncontrolled studies do show improvement in some children with NMSE, presumably because many of these children have a reduced functional bladder capacity (Caione et al, 1997; Nevéus, 2001). There is also some evidence that nocturnal detrusor overactivity (especially without nocturnal polyuria) plays a role in the pathogenesis of enuresis and therefore makes anticholinergics an attractive pharmacotherapeutic option (Nevéus, 2001).

Where anticholinergics clearly do have a role is combination therapy in the treatment of children who are refractory to DDAVP monotherapy. In the first randomized, placebo controlled study of combination therapy with anticholinergics, Austin and colleagues (2008) studied 34 children with primary MSE who failed maximal-dose DDAVP monotherapy and assigned them, in a double-blind manner, to receive either extended-release tolterodine or placebo while all children continued to take DDAVP. Patients were reassessed after 1 month of therapy with a 1-week nocturnal record. They found a significant reduction in the mean number of wet nights in the combination therapy group compared to the placebo group. With a generalized estimating equation approach, there was a significant 66% reduction in the risk for a wet episode compared with the placebo group. Recently, Montaldo and associates (2012) reported their results in 206 children with MSE refractory to DDAVP monotherapy who were randomized to 5 mg of oxybutynin or placebo and followed for 1 month. As predictive factors, bladder

In a recent systematic review, treatment with TCAs was associated with a reduction of approximately one wet night per week compared to placebo ([Glazener and Evans, 2000](#)). Approximately 20% of children became dry during therapy versus 5% with placebo. The rate of relapse was 96% after discontinuation of therapy. In an observational study of children who were refractory to first-line therapy, researchers found that approximately one third of children became dry on monotherapy, one third became dry after adding DDAVP, and the remaining third were nonresponders ([Gepertz and Nevéus, 2004](#)).

volume and wall thickness index, nocturnal polyuria, and voiding latency were considered. Corroborating the original study by Austin and associates, the oxybutynin group showed a higher rate of full and partial responses than the placebo group. The responders to combined oxybutynin and desmopressin had a significantly lower bladder volume and wall thickness index than nonresponders.

Combination Therapy

The efficacy of the enuresis alarm plus desmopressin combination has been investigated in a number of studies (Sukhai et al, 1989; Bradbury, 1997; Leebeek-Groenewegen et al, 2001; Fai-Ngo et al, 2005).

Please see the Expert Consult website for further details.

A reduction in the number of wet nights is consistently observed when using combination therapy of desmopressin and the moisture alarm compared to monotherapy. Enuresis relapse, however, is noted in some patients with long-term follow-up.

Alternative Therapies

Other drugs, including indomethacin, ephedrine, atropine, furosemide, and diclofenac, have been tried in the treatment of enuresis. A recent systematic review of randomized trials of drugs other than TCAs and DDAVP found that although indomethacin, diclofenac, and diazepam were better than placebo in reducing the number of wet nights, none of the drugs was better than desmopressin (Deshpande et al, 2012). A second recent review of complementary approaches such as hypnosis, psychotherapy, and acupuncture found limited evidence from small trials with methodologic limitations to support the use of such modalities for the treatment of enuresis (Huang et al, 2011).

KEY POINTS: ENURESIS

- The majority of children who present with enuresis have the nonmonosymptomatic form.
- The spontaneous resolution rate of enuresis is approximately 15% annually, such that only approximately 1% of teenagers will continue to be afflicted.
- Enuresis stems from a maturational delay in the ultimate development of bladder control, with three organ systems implicated in its pathogenesis: the bladder, the kidney, and the brain.
- The basic evaluation of the child with MSE includes history (including a voiding diary), physical examination, and urinalysis. The principal objective of the evaluation is to rule out BBD or enuresis as a manifestation of an underlying medical disease (e.g., posterior urethral valves, spinal dysraphism, diabetes mellitus) and to identify that the enuresis is truly monosymptomatic.
- Conventional therapies for enuresis include behavioral modification, the enuresis moisture alarm, and pharmacologic therapy (e.g., desmopressin, anticholinergics, imipramine).

Sukhai and colleagues (1989) reported a crossover trial of 28 children with primary MSE who were blindly allocated at random to a combination of enuresis alarm plus 20 µg intranasal DDAVP or alarm plus placebo for 2 weeks. Patients received the other therapy after a 2-week treatment-free period. The combined treatment of desmopressin plus enuresis alarm resulted in significantly more dry nights per week during the 2 weeks of observation than placebo plus the alarm. Although there was a significant difference between groups, the treatment period of 2 weeks was most likely too short for alarm therapy to contribute significantly to the outcome variable.

Bradbury compared the efficacy of enuresis alarm monotherapy to alarm treatment in combination with 40 µg DDAVP nasal spray (Bradbury, 1997). At the end of the treatment period, children receiving combination therapy had more dry nights per week (mean: 6.1) than children using an alarm alone (mean: 4.8). In addition, more children achieved an initial success (4 weeks of dryness) after combination treatment (27 children [75%]) compared with alarm monotherapy (16 children [46%]). Interestingly, this improvement was most pronounced in children with severe wetting (>5 nights per week), family problems, or behavioral problems.

In a placebo-controlled study containing 93 patients with MSE, Leebeek-Groenewegen and colleagues (2001) compared 9 weeks of desmopressin plus alarm therapy with alarm monotherapy. They showed a significant decrease in the number of wet nights per week with combination therapy. After 6 months of follow-up, however, they reported that there was no significant difference between the two treatment groups regarding the efficacy and number of children who relapsed.

In a recent multicenter randomized controlled trial, Fai-Ngo et al (2005) compared the efficacy of the enuresis alarm, oral DDAVP, and combined treatment in children with primary MSE. They assigned 105 children equally among groups to receive treatment for 12 weeks, and patients were then followed for 12 weeks after treatment. They found that the mean number of wet nights per week was significantly lower in the combination group than in the other groups at the conclusion of therapy. Desmopressin produced an immediate effect but relapses were most common in the DDAVP monotherapy and combination therapy groups (60% and 40%, respectively). Alarms took several weeks to produce a benefit, but this was sustained on follow-up (20% relapse rate).

Epidemiology and Classification of Disorders of Defecation

Normal versus Abnormal Bowel Function

Evaluation of Abnormalities of Defecation

Imaging Studies

Management

Prognosis

Surgical Management

At first glance, a bowel management chapter may appear out of place in a textbook discussing urology. However, clinical experience has called attention to a deep interrelation between urinary and bowel function. Indeed the past decade has witnessed a greater understanding of the pelvic floor, seeing it as working as a functional unit blending the artificial barriers set by specialty training. The lower gastrointestinal and genitourinary tracts share embryological origin, anatomic location, innervation (both motor and sensory), volitional control with normal development, and sphincteric mechanisms. On clinical grounds this is evidenced during careful history and examination, with frequent dual dysfunction in neurologic conditions (neuropathic bladder and bowel in disease processes of the lower spinal cord), bladder capacity compromise resulting from a distended rectum (Fig. 144-1), and dysfunctional elimination rarely affecting only one system (instead often seeing concurrent urinary and bowel symptomatology in affected children). Thus understanding of urinary tract dysfunction is incomplete without taking into account and addressing all aspects of elimination, including defecation.

Anomalies of the bowel and urinary tract frequently coexist, whether functional, anatomic, and/or neuropathic. Constipation and rectal distention might adversely impact bladder function (Burgers et al, 2010), leading to low functional bladder capacity, incontinence, and predisposition for urinary tract infections, and constipation and rectal distention might also trigger or exacerbate vesicoureteral reflux (Fig. 144-2 on the Expert Consult website) (Yazbeck et al, 1987, Loening-Baucke, 1997). In addition, constipation is a common side effect of medications used to manage lower urinary tract symptoms (anticholinergics). Because of this common association, pediatric urologists during the past few decades have become comfortable with assessing and managing bowel problems in the everyday care of children and adolescents who have genitourinary complaints. In particular, contemporary management of children with dysfunctional elimination calls for routine simultaneous assessment of the gastrointestinal and genitourinary tract. Good understanding of both medical and surgical options is also warranted, as it is often the urologist who is in position to manage both urinary and fecal problems synchronously (Burgers et al, 2013).

EPIDEMIOLOGY AND CLASSIFICATION OF DISORDERS OF DEFECATION

Defecation disorders are common throughout life, and childhood is not an exception. In children, these are most often manifested

KEY POINTS: INTRODUCTION

- The bladder is not an isolated organ. On the contrary, it works in close functional and anatomic relationship with surrounding structures, including the lower gastrointestinal tract.
- Constipation is common yet hard to ascertain just by asking children or parents.
- Neurologic problems can affect both systems, as evident in patients with neuropathic bladder dysfunction.
- Medications commonly used for bladder management have an adverse impact on bowel function (most notably anticholinergics).
- Based on the referral pattern, pediatric urologists are in a privileged position to address bowel function effectively and to produce a positive impact on the child's well-being and quality of life.

as infrequent bowel movements without a specific underlying organic etiology; thus these are labeled as “functional” constipation. Reported prevalence in the pediatric population ranges between 0.7% and 29.6%, with no significant difference in rates for boys and girls (van den Berg et al, 2006). This condition is a frequent reason for evaluation by family medicine health care providers, pediatricians, pediatric gastroenterologists, pediatric surgeons, and—because of associated lower urinary tract symptoms—pediatric urologists. Common presenting symptomatology includes infrequent defecation, abdominal bloating or distention, painful bowel movements, abdominal pain, and fecal incontinence (Nurko and Scott, 2011). Although there are multiple potential etiologies (Box 144-1), most children have a negative assessment for associated conditions. Nevertheless, concerns regarding an organic cause often trigger an overtly extensive, occasionally invasive, and expensive workup. In essence, functional constipation is a diagnosis of exclusion, defined as a defecation disorder not associated with congenital or acquired abnormalities or specific medications.

Of all the functional gastrointestinal disorders of childhood—irritable bowel syndrome (IBS), functional bloating, functional constipation, and functional diarrhea (Longstreth et al, 2006)—constipation is the condition most frequently encountered by pediatric urologists, and this demands expertise in management along with ruling out other pathologies that require specialized assessment and treatment. Thus modern management in specialized centers should include health care providers who are comfortable with addressing common elimination disorders.

Figure 144-2. Voiding cystourethrogram in a patient with dysfunctional elimination and recurrent episodes of pyelonephritis. Note the presence of bilateral vesicoureteral reflux (*white arrows*) and “spinning top” deformity of the bladder neck during voiding (*black arrow*). Patient previously underwent a motility study because of persistent constipation despite stool softeners (note encircled radiopaque markers).

Figure 144-1. Pelvic ultrasound demonstrates anterior displacement of the bladder wall with decrease in functional bladder capacity as a result of a large amount of fecal material in the rectum (arrows).

BOX 144-1 Differential Diagnosis of Chronic Constipation

- Idiopathic or functional
- Behavioral: Dysfunctional elimination resulting from defecation avoidance, intellectual disability, psychological problems, adverse life event(s)
- Poor dietary habits: Low fluid and fiber intake
- Structural defects: Anorectal malformation, anal stenosis, Hirschsprung disease, extrinsic compression by pelvic mass, deficient abdominal musculature (most notably, prune-belly syndrome)
- Neurologic disorders: Isolated to spinal cord (myelomeningocele, tethered cord, trauma, transverse myelitis, postsurgical, tumors), cerebral palsy, muscular dystrophy, neurodegenerative disorders
- Endocrine disorders associated with chronic dehydration (such as diabetes insipidus) and electrolyte disorders (most notably hypercalcemia and hypokalemia), hypothyroidism, hypervitaminosis D
- Cystic fibrosis
- Celiac disease
- Connective tissue disorders (such as Ehlers-Danlos syndrome)
- Food intolerance (cow's milk) and other food allergies
- Medications: Anticholinergics, opioid analgesics, anticonvulsants, antidepressants and antipsychotics, iron and calcium supplements, antispasmodics, diuretics
- Other bowel motility disorders: Colonic dysmotility, chronic pseudo-obstruction

NORMAL VERSUS ABNORMAL BOWEL FUNCTION

The definition of normal bowel function has to be framed within the context of age, developmental issues, and cultural expectations. Although seemingly simple, normal bowel function is often difficult to define and ascertain. There is expected variation in toilet-training age; nevertheless, children are generally expected to begin to experiment at age 2 and to gain control of the defecation process completely by age 3 (Wald et al, 2009). After this age, frequency varies from three stools per week to three stools per day (under normal circumstances), with the majority of normal children 5 to 8 years of

BOX 144-2 Rome III Diagnostic Criteria for Functional Constipation

In the absence of organic pathology, ≥ 2 of the following must occur:

- A. For a child with a developmental age <4 yr (Criteria fulfilled for at least 1 mo)
 1. ≤ 2 defecations per wk
 2. At least 1 episode of incontinence per wk after the acquisition of toileting skills
 3. History of excessive stool retention
 4. History of painful or hard bowel movements
 5. Presence of a large fecal mass in the rectum
 6. History of large-diameter stools that may obstruct the toilet

Accompanying symptoms may include irritability, decreased appetite, and/or early satiety, which may disappear immediately following passage of a large stool.
- B. For a child with a developmental age ≥ 4 yr with insufficient criteria for irritable bowel syndrome (Criteria fulfilled at least once per wk for at least 2 mo before diagnosis)
 1. ≤ 2 defecations in the toilet per wk
 2. At least 1 episode of fecal incontinence per wk
 3. History of retentive posturing or excessive volitional stool retention
 4. History of painful or hard bowel movements
 5. Presence of a large fecal mass in the rectum
 6. History of large-diameter stools that may obstruct the toilet

age having a bowel movement daily or every other day without straining or withholding (Fontana et al, 1989; Wald et al, 2009). Unfortunately, children with irregular, incomplete, and/or infrequent defecation may not report symptoms; parents are often surprisingly unaware of their child's bowel routine. To aid with assessment, the presence of constipation should be ascertained with standardized diagnostic tools such as the Rome III criteria (Box 144-2) (Hyman et al, 2006; Rasquin et al, 2006). These criteria take into account three important considerations: absence of an organic underlying cause, developmental age, and duration of symptoms.

EVALUATION OF ABNORMALITIES OF DEFECATION

A good history and physical examination are the cornerstones of evaluation and they may suffice for the diagnosis and initial management of most children. A detailed previous medical history is clearly relevant. Critical information to actively gather includes age of onset of symptoms, failure to toilet-train within an age-appropriate and developmental timeframe, frequency of bowel movements, stool consistency (assessed by appearance and preferably recorded with existing stool scales, such as the Bristol Stool Form scale [Lewis and Heaton, 1997; Longstreth et al, 2006] [Fig. 144-3] or the scale's pediatric modifications [Chumpitazi et al, 2010; Lane et al, 2011]), pain with defecation, bleeding per rectum, presence and characteristics of associated abdominal pain, fecal incontinence, holding behaviors, dietary history, changes in appetite, nausea or vomiting, weight loss, growth pattern (including height and weight), developmental delay, and failure to thrive. The age of onset of symptoms is one of the easiest and most important pieces of information to obtain, as it can be an important indicator for underlying pathology (Box 144-3). A detailed previous surgical history is also of great value, and attention should be paid to previous correction of anorectal malformations, resection of sacrococcygeal teratomas or other pelvic tumors, closure of spinal dysraphism, spinal cord untethering, and genitourinary reconstruction for conditions such as prune-belly syndrome.

Type 1		Separate hard lumps, like nuts (hard to pass)
Type 2		Sausage-shaped but lumpy
Type 3		Like a sausage but with cracks on the surface
Type 4		Like a sausage or snake, smooth and soft
Type 5		Soft blobs with clear-cut edges
Type 6		Fluffy pieces with ragged edges, a mushy stool
Type 7		Watery, no solid pieces. Entirely liquid

Figure 144-3. The Bristol Stool Form scale.

BOX 144-3 Warning Signs and Symptoms

- Constipation, fecal impaction that predates bowel training, particularly in the first year of life*
- Chronic or recurrent respiratory problems†
- Need for medications or rectal stimulation in the first year of life, particularly breast-fed infants
- Bloody stools
- Alternating constipation and diarrhea
- Severe or constant abdominal pain
- History of bowel obstruction
- Associated weight loss, growth retardation, failure to thrive‡
- Hypotonia, developmental delay§
- Decreased appetite, early satiety
- Bilious vomiting
- Ribbon-like stools
- Fecal and urinary incontinence beyond age of toilet training
- Associated neurologic symptoms, particularly in the lower extremities (weakness, gait abnormalities, muscle atrophy, sensory abnormalities)
- Lower back abnormalities (sacral dimple, lipoma, hair tuft, gluteal cleft deviation)
- Explosive stool and air from rectum after stimulation (digital, suppository) or following rectal examination

*Onset of symptoms in infants younger than 1 month old or delayed passage of meconium by 48 hours in a term neonate should raise suspicion for an organic condition, specifically Hirschsprung disease (Ghosh and Griffiths, 1998), and ruling out the diagnosis with a rectal biopsy should be considered.

†Suspect cystic fibrosis.

‡Suspect celiac disease, hypothyroidism, and Hirschsprung disease.

§Associated with hypothyroidism and trisomy 21.

Critical components of physical examination include appearance of the perianal region and perineum, abdominal examination (including presence of palpable masses, muscle tone, distention, pain on examination), presence of a cremasteric and anal reflex, gluteal cleft and sacral region assessment (for hair tufts, deviated gluteal cleft [Fig. 144-4 on the Expert Consult website], sacral dimples [Fig. 144-5 on the Expert Consult website], flat buttocks [Fig. 144-6 on the Expert Consult website]), and lower extremity examination (weakness, coordination, muscle atrophy, decreased muscle strength, abnormal deep tendon reflexes, gait abnormalities). Although prune-belly syndrome is often an obvious diagnosis on physical examination, the presence of cryptorchidism (or previous bilateral orchidopexies for intra-abdominal gonads), lax abdominal wall, and lower urinary tract problems should raise concern for prune-belly syndrome, and abdominoplasty should be assessed appropriately and considered as a means for addressing the difficulty in generating increased intra-abdominal pressure for defecation.

Physical examination should also include weight and height (parameters graphed against normal growth curves) and inspection of the anal region (anal position, stool present around the anus or on the underwear, signs of trauma, anal fissures, sensation). Although potentially considered an integral part of a complete physical examination, digital rectal examination should not routinely be conducted in children. It is reserved for difficult-to-treat cases and should be performed by health care professionals comfortable with interpreting features of anorectal anatomic abnormalities (Mugie et al, 2011) to evaluate specifically for anal stenosis, a large fecal mass, or an empty rectum. Extreme fear during anal inspection, fissures, or signs of trauma should raise suspicion for sexual abuse.

Assessment of patients with functional constipation should be reassuringly normal. The expected findings are those of a generally well-appearing child, with weight and height within normal limits, normal appearance of anus and surrounding area, a soft abdomen (occasionally distended or with a palpable fecal mass in the left lower abdominal quadrant), normal appearance of the skin and anatomic structures of lumbosacral/gluteal regions, normal gait, normal tone strength, and normal lower limb reflexes. In addition, these patients should not exhibit clinical manifestations until at least a few months of life, having a history of normal passage of meconium (within the first 24 to 48 hours after birth). Presentation will sometimes coincide or worsen with precipitating factors, such as change in diet (e.g., transitioning out of breastfeeding), new medications (such as anticholinergics for management of urinary frequency), or psychosocial stressors (i.e., moving, starting or changing school, parents separating, new sibling, major illness in family, travel).

Aside from abnormalities on physical examination, based on history and ancillary tests there are selected children who should undergo a specific workup for organic conditions that manifest themselves or are associated with elimination problems. These include cystic fibrosis, hypothyroidism, celiac disease, dietary allergies, Hirschsprung disease or colonic aganglionosis, anal stenosis, and trisomy 21. Laboratory evaluation in refractory cases or in cases with associated worrisome findings includes celiac screening and thyroid function tests (TSH, T₄). In older children and teenagers, other conditions should be added to the differential, such as mental health issues (depression), eating disorders, sexual abuse, and IBS (Longstreth et al, 2006). IBS, a functional bowel disorder, presents with abdominal pain associated with defecation or a change in bowel habits, and diagnosis depends on key temporal relationships: recurrent abdominal discomfort for at least 3 days per month in the last 3 months that is associated with improvement with defecation, and onset or worsening with a change in frequency or stool form (appearance).

IMAGING STUDIES

Although of modest clinical value, along with exposure to a very low dose of radiation, abdominal radiographs are commonly used

Figure 144-4. Deviated gluteal cleft in a child with neuropathic bladder and bowel dysfunction secondary to cord tethering and occult dysraphism.

Figure 144-5. Sacral dimple (*arrow*).

Figure 144-6. Sacral agenesis. A, Findings on physical examination, including a “flat” appearance of the buttocks, associated with neuropathic bladder and bowel. B, Lateral-view lumbosacral radiograph with bony defects of the lower spine consistent with sacral agenesis (or caudal regression syndrome).

Figure 144-7. Abdominal radiograph demonstrating fecal loading throughout the colon (asterisks) in a child, resulting in abdominal distention, encopresis, and urinary frequency.

Figure 144-8. Abdominal radiograph with evidence of fecal impaction (asterisks) in a child who presented with acute urinary retention (note placement of suprapubic tube for bladder management).

in the diagnosis and management of defecation disorders, particularly constipation. The sensitivity and specificity of abdominal radiography in diagnosing childhood constipation is far from optimal, ranging from 60% to 80% and 40% to 90%, respectively (Reuchlin-Vroklage et al, 2005; Mugie et al, 2011). The test is clearly subjective to interpretation, and findings depend on the time since the child's last evacuation. Nevertheless, scales have been devised to help standardize evaluations, based on estimated bowel dilation, as well as the pattern, amount, and distribution of feces in the colon, and these scales provide scores that can be useful for diagnosis, monitoring, and research (Barr et al, 1979; Blethyn et al, 1995; Leech et al, 1999; van den Bosch et al, 2006). Proponents who favor routine radiologic assessment argue that the study can demonstrate clearly the amount of fecal loading, can delineate stool distribution throughout the colon and rectum (Fig. 144-7), as well as can help ascertain the presence of fecal impaction (which includes important therapeutic implications) (Fig. 144-8). In addition, it may also show associated pathologies, such as bony abnormalities indicative of occult spinal dysraphism or sacral agenesis (Fig. 144-9 on the Expert Consult website), and might help provide a visual aid for family and patient recognition of stool retention despite a history of regular defecation. In turn, this can be useful to maximize adherence to treatment in cases where there is disagreement or disbelief regarding the presence of constipation (particularly if patient is consulting solely for lower urinary tract symptoms or urinary tract infections). Serial examinations may also provide an objective means to monitor response to disimpaction and/or maintenance treatment (taking "as low as reasonably achievable" radiation exposure principle into account), although many would contend that the consideration of symptomatic improvement alone is sufficient. In some circumstances, the study can be replaced or enhanced by conducting ultrasound evaluation of the lower abdomen and pelvis, which assesses fecal loading behind the bladder as an alternative or adjunct marker for constipation (Klijn et al, 2004; Joensson et al, 2008) (Fig. 144-10). Ultimately, if constipation and fecal impaction or loading is obvious on history and

Figure 144-10. Assessment of fecal load in rectum during pelvic ultrasound. Stool is seen behind the bladder (arrows). Note bladder distention caused by incomplete emptying and infrequent voiding resulting from toilet avoidance secondary to pain with defecation.

physical examination, management based on clinical grounds without imaging studies is reasonable and is recommended in routine practice (Tabbers et al, 2014).

Colonic transit time studies, which evaluate the progression of radiopaque markers along the gastrointestinal tract with serial radiographs, are not recommended for routine diagnosis of functional constipation. However, in difficult-to-treat or unresponsive cases this study may have some value, as a normal evaluation in the setting of fecal incontinence would suggest either nonretentive

Figure 144-9. Bony abnormalities detected on abdominal radiograph during assessment of difficult-to-treat constipation. **A,** Lumbar bony defects consistent with occult spinal dysraphism. **B,** Absent sacrum, suggestive of sacral agenesis.

Figure 144-11. Soluble contrast enema for evaluation of child with defecation problems since birth. Findings suggestive of Hirschsprung disease, including massively distended colon and rectum that can progress toward more normal-appearing large bowel (arrows). This child was subsequently assessed with a rectal biopsy to confirm the diagnosis.

defecation disorder or an unreliable medical history. Additional studies are selectively obtained based on suspicion for an underlying condition. A contrast enema series can be of value in evaluating children with characteristics suggestive of Hirschsprung disease (Reid et al, 2000; Langer, 2013) (Fig. 144-11) and repaired congenital anatomic abnormalities (i.e., anorectal malformation); concern for a neuropathic process and/or lower spine stigmata should be evaluated with a spine ultrasound (if detected before calcification of the vertebral bodies in the first 3 to 6 months of life) (Fig. 144-12 on the Expert Consult website) or lumbosacral magnetic resonance imaging in older children (Fig. 144-13 on the Expert Consult website), and suspicion for sacral agenesis should be further assessed with a lateral-view lower spine/pelvis radiograph (see Fig. 144-6 on the Expert Consult website).

If Hirschsprung disease or colon aganglionosis is suspected, a deep suction biopsy (including submucosal) should be obtained (Langer, 2013), favoring a transanal approach and aiming at a location 2 to 3 cm from the dentate line. Diagnosis is supported by the absence of ganglion cells, by hypertrophied nerve fibers, and by an increase in acetylcholinesterase activity in the lamina propria and muscularis mucosa. Anorectal manometry is useful only in selected cases (Noviello et al, 2009), such as suspected Hirschsprung disease and internal sphincter achalasia. In these conditions, the rectoanal relaxation reflex is absent. Nevertheless, in patients suspected of having functional constipation, manometry adds little to the diagnosis or therapeutic strategy (van Ginkel et al, 2001).

MANAGEMENT

As is the case with many other conditions, careful thought and consideration must be first directed toward more conservative, non-operative management alternatives (Fig. 144-14). A medical plan,

KEY POINTS: EPIDEMIOLOGY AND CLASSIFICATION OF DISORDERS OF DEFECATION

- The Rome III criteria are recommended for diagnosis of functional constipation in children.
- The diagnosis of functional constipation should be mostly based on a good medical history and physical examination.
- The presence of alarm signs or symptoms or intractable constipation should trigger a focused assessment to diagnose underlying medical conditions.
- Routine use of abdominal radiographs is of limited value and should be reserved for selected cases, such as suspected fecal impaction and difficult or unreliable history and physical examination.

consisting of behavioral interventions, dietary changes, stool softeners and laxatives, and judicious use of retrograde enemas, is often sufficient to manage most patients with chronic constipation. In addition, education about defecation and demystification of toilet training (in children with a developmental age of at least 4 years) are crucial, and these are often overlooked as components of successful management (van der Plas et al, 1997). Clearly, whether a functional problem or a problem associated with an organic underpinning—especially considering the spectrum of associated urologic disorders—an individualized approach to patients is preferred.

Treatment of constipation is often started within the context of lower urinary tract symptoms. The association between the two has gained acceptance, and simultaneous assessment is part of the comprehensive evaluation offered in many pediatric urology practices, often run by nurse practitioners and other health care providers. The concept's popularity is based on data from a landmark study by Loening-Baucke (1997), who reported on 234 consecutive patients with constipation and encopresis and associated urinary incontinence and urinary tract infections. Successful relief of constipation in 52% of patients was associated with the resolution of daytime urinary incontinence in 89%, the resolution of nocturnal enuresis in 63%, and a resolution of infections. Although supported by experience and other subsequent case series—demonstrating improvement in incontinence episodes, voided volume, and post-void residuals (Erickson et al, 2003)—the value of the universal use of laxatives in children presenting for treatment of overactive bladder symptoms has been called into question in a randomized control trial (Bush et al, 2013). Nevertheless, if constipation is suspected, treatment should be recommended, as highlighted by the Standardization Committee of the International Children's Continence Society (Burgers et al, 2013).

Nonpharmacologic Interventions

If screening and imaging studies are negative, thus restricting the diagnosis to a functional elimination problem and/or slow colonic transit time, medical management follows a stepwise process that begins with medical therapy coupled with behavioral modifications; this process includes adequate fluid and fiber intake, regular defecation, scheduled postmeal attempts to take advantage of an increase in colon motility in response to gastric distention and the digestive process (so-called gastrocolic reflex), relaxation techniques and proper positioning in the toilet (with good foot support and forward leaning to flex thighs closer to the abdomen and to generate better an increase in abdominal pressure). Obviously, in cases where an underlying organic etiology is suspected, specific therapy should be sought following a directed workup.

Behavioral and dietary recommendations are often implemented first and may suffice as a stand-alone strategy or as an adjunct to medical or surgical interventions. The impact of these is difficult to measure because of wide differences in the protocols used, a high placebo response rate in some subgroups (Bush et al, 2013),

Figure 144-13. Magnetic resonance imaging of lumbosacral region in a child with abnormal lower back examination during initial assessment of constipation and urinary frequency. Note presence of lipoma extending into the spinal canal (*arrows*).

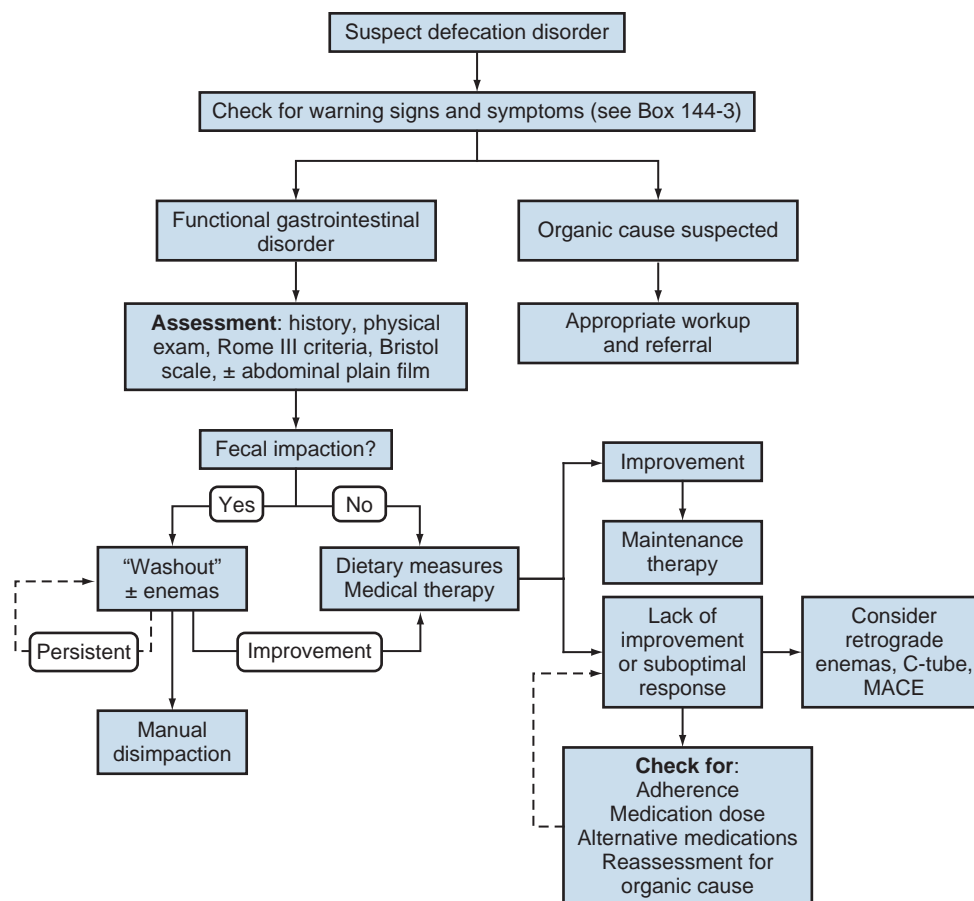

Figure 144-14. Management algorithm for childhood defecation disorders seen in a pediatric urology practice. Lack of improvement or intractable constipation should be diagnosed based on worsening response, absence of response, or suboptimal response to adequate medical treatment for at least 3 months. C-tube, cecostomy tube; MACE, Malone antegrade continence enema procedure.

and attrition (patient lost for follow-up). Nevertheless, a lack of benefit is often based on limited data; families commonly attempt therapeutic trials without recommendation or supervision by a health care provider, parents often favor nonpharmacologic strategies despite unproven benefit, and side effects are often mild or negligible. Thus the expectation is that early on, children will be asked to implement generous fluid intake (in accordance with expectations for children with lower urinary tract symptoms), to optimize diet (including liberal fiber intake in the form of fruits and vegetables), to establish a bowel routine taking advantage of gastrocolic reflex, to ensure active lifestyle (promoting physical activity and avoid sedentary tendencies), and to consider the use of prebiotics and/or probiotics (Chmielewska and Szajewska, 2010; Korterink et al, 2013), additional fiber intake (Staiano et al, 2000; Loening-Baucke et al, 2004; Castillejo et al, 2006; Chmielewska et al, 2011), or biofeedback (van der Plas et al, 1996a, 1996b). Unfortunately any positive effect on functional constipation is difficult to propose based on high-quality data (Tabbers et al, 2011), and treatment algorithms tend to be based on opinion rather than evidence (Pijpers et al, 2010).

The chronic nature of defecation disorders, in combination with fears of adverse effects or irreversible reliance on daily medication use, contributes to the search for some form of alternative treatment in approximately 40% of children with functional constipation (Vlieger et al, 2008). Many of these, aside from having unknown effectiveness, can be associated with important complications or discomfort (hypnotherapy, acupuncture, homeopathy, osteopathic or chiropractic musculoskeletal manipulations, transcutaneous nerve stimulation), and should be avoided or only

used under a research setting until confirmed by well-designed studies. In particular, phytotherapy (favored by parents who equate “natural” with safety) can elicit severe adverse reactions because of contamination, inability to quantify active compounds, unknown adulteration, or direct toxic effects.

Disimpaction and Large Bowel/Rectum Washout

Decreasing fecal load in the large intestine and rectal vault is the first step toward establishing an optimal medical regimen. Impaction is defined as the presence of a hard mass in the lower abdomen and/or left lower quadrant, or a dilated rectum filled with a large amount of stool as determined by rectal examination, pelvic ultrasound, or abdominal radiography, irrespective of the ability to produce bowel movements. The child may be able to pass some stool without effectively emptying, and on occasion may have loose bowel movements that can be paradoxically (and erroneously) labeled or treated as diarrhea. Approximately 30% of children with long-lasting functional constipation present with fecal impaction, which is frequently associated with stool incontinence (Mugie et al, 2011; Nurko and Scott, 2011). The presence of fecal impaction demands attention before the initiation of maintenance medical management; otherwise treatment will fail or paradoxically worsen the gastrointestinal symptoms.

Disimpaction and bowel washout, as the names imply, attempt to address the problem in a relatively short time, accepting the need for enemas or stimulants, and tolerating temporary worsening of fecal incontinence, abdominal distention, and discomfort. In stark contrast to maintenance therapy, enemas and suppositories are

acceptable as routine interventions during this period and may facilitate evacuation of a large/hard fecal load in the rectum. Although subject to variability based on the amount of fecal material, distribution within the colon, child's age, tolerance for medication administration per anus, provider experience, and cultural barriers, common programs include "high-dose" polyethylene glycol (PEG, 1 to 1.5 g/kg/day for 3 to 6 days) with or without sodium chloride, sodium phosphate, or mineral oil enemas (daily for 3 to 6 days) (Tabbers et al, 2014). The ultimate goal is to produce soft, watery bowel movements with correction of abdominal distention, palpable fecal mass on abdominal or rectal examination, and clearance of fecal load as determined by abdominal plain film or pelvic ultrasound.

In rare circumstances clearance can only be achieved with more aggressive medication administration that is conducted while admitted to the hospital and aided by nasogastric tube delivery and intravenous fluids to prevent dehydration (similar to local protocols for preoperative bowel preparation). If this treatment fails, is not tolerated, or is associated with severe pelvic pain resulting from difficulty in passing a hard, large rectal "fecaloma," digital disimpaction under anesthesia may be required. Subsequent outpatient management requires regular (often daily) visits, and consists of monitoring response while modifying the volume and content of the retrograde enemas to suit the individual needs of each patient. Normal saline is commonly used as the solution for enemas, with additives used based on preference and familiarity with use (glycerin, soap, or phosphate). Commercial sodium phosphate formulations (such as the Fleet enema) can be added in difficult cases, but these should be used with caution in children with renal impairment. Dosage is adjusted by age: 30 mL for children less than 4 years old, 60 mL for children 4 to 10 years old, and 120 mL for children older than 10 years. The total volume of the enema must be tailored to effect, with constipated patients often requiring up to 500 to 1000 mL. Management is considered successful when the underwear remains clean for 24 hours.

Maintenance Therapy

Before beginning any maintenance protocol, the provider should verify that the rectosigmoid is not impacted again, despite what was thought to be an adequate washout. Failure to do so means that management is bound to fail, paradoxically leading to overflow fecal incontinence or triggering pain and cramping with oral medications. In contrast to the management of fecal impaction, routine rectal administration of medications is avoided as first-line maintenance therapy. Although tolerated by some children, the use of enemas instead of optimal oral medical therapy does not appear to provide added benefit (Bongers et al, 2009). There is, however, limited place for routine use of enemas, suppositories, or rectal stimulation except for in severe, difficult-to-treat cases.

Osmotic laxatives—such as lactulose, milk of magnesia, and PEG—are usually sold as solutions or powders to be dissolved in water, thus making them relatively easy to administer to children and making them the preferred agents. They act as poorly absorbed hyperosmolar molecules, increasing stool water content (making feces softer and easier to pass), and increasing colonic peristalsis. Stimulant laxatives (sodium picosulfate, senna, and bisacodyl), which act directly on the intestinal mucosa, increase water and electrolyte secretion and are often reserved for second-line or adjunct (intermittent) protocols, used only in selected (otherwise refractory) circumstances.

With the introduction of PEG into routine clinical practice, tolerance of medical management has improved, and it is currently the preferred agent in many centers. PEG is better tolerated and easier to administer than alternative medications such as lactulose, mineral oil, and milk of magnesia (magnesium hydroxide) (Gordon et al, 2012, 2013). Maintenance PEG dose is 0.2 to 0.8 g/kg/day, further adjusted based on clinical response, and administered with fluids either once or twice daily. It is virtually tasteless and dissolves easily within seconds. The most common side effect, watery stools or diarrhea, can be easily addressed by

scaling back the dose administered daily. As an alternative if PEG is not available, lactulose (1 to 2 g/kg, once or twice daily) can be used (Tabbers et al, 2014).

New medications are being introduced in the therapeutic armamentarium. These have been mostly studied in the adult population, yet they are expected to transition slowly into pediatrics. New molecules include lubiprostone, linaclotide, and prucalopride (Tabbers et al, 2014). Prucalopride, an oral selective high-affinity 5-HT₄ receptor antagonist with gastrointestinal prokinetic activities, shows particular promise and may represent a reasonable choice for children who fail to respond to more conservative measures (Winter et al, 2013).

Maintenance treatment should continue for at least 2 months, and symptoms should completely resolve for at least 1 month before attempting gradual slow discontinuation. If the child is in the process of toilet training, medication should only be stopped after this developmental milestone has been completely achieved without evidence of defecation problems. Lack of improvement or worsening should alert the provider to the possibility of reimpaction, lack of adherence with the prescribed medications, insufficient dose, or the introduction of new medications that may worsen constipation. The development of new symptoms, new findings on physical examination, or failure to improve should also raise again consideration for underlying organic causes. Refractory cases are most commonly characterized by recurrent fecal impaction, likely resulting from retentive posturing, anal sphincter dyssynergia, and abnormal rectal motility or function (Youssef and Di Lorenzo, 2002; Voskuijl et al, 2006; Bongers et al, 2009).

PROGNOSIS

Functional constipation can be a difficult-to-treat and long-lasting problem for some children. Nevertheless, with adequate management nearly 50% of patients monitored for 6 to 12 months can recover and successfully discontinue medications, whereas in up to 80% the condition can be adequately controlled with routine interventions (Pijpers et al, 2010). Unfortunately, **subsequent recurrences are fairly common, with up to 50% of children experiencing an episode in the first 5 years after successful treatment** (Loening-Baucke, 1993; van Ginkel et al, 2003). There is a paucity of data on reliable prognostic factors—such as defecation frequency—that could identify patients at risk (Pijpers et al, 2010). Reported figures are clearly impacted by the included patient population, and specialized referral centers may evidence lower cure rates despite intensive medical and behavioral therapy, with some children experiencing persistent symptoms beyond puberty, particularly those with older age of onset and initial delay in treatment (Bongers et al, 2010). Importantly, approximately 80% of children adequately managed early in their course recover without the need

KEY POINTS: MANAGEMENT AND PROGNOSIS

- Adequate fluid and fiber intake, nonsedentary physical activity, education, and guidance for toilet training should be presented as first-line interventions for all children of adequate developmental age.
- Although of debatable value, interventions with low risk for adverse effects, such as behavioral therapy or biofeedback, can be considered for interested families.
- PEG should be considered as first-line treatment for constipation (both for initiation and maintenance).
- Enemas are of value in the short-term management of children with fecal impaction, but are not recommended for routine maintenance treatment.
- Treatment can be gradually discontinued in patients who remain symptom free for at least 1 to 2 months, with vigilance required regarding recurrence.

for medications at 6-month follow-up, compared with only 30% who experience a delay in treatment (i.e., initial medical treatment postponed for >3 months) (Pijpers et al, 2010). Ultimately, data clearly suggest that constipation without treatment does not improve with time or after puberty (van Ginkel et al, 2003). Early adequate therapeutic interventions are beneficial and may contribute to a successful long-term outcome while improving the child's quality of life.

SURGICAL MANAGEMENT

A small group of children fail medical management, and they may be considered candidates for surgical options. Surgical management of difficult-to-treat defecation disorders is not a new concept, and it has progressed from diversion (colostomy) for the most severe cases to liberal use of enemas and aggressive colon evacuation. With the introduction of the antegrade continence enema (ACE) or the Malone antegrade continence enema (MACE) procedure in 1989, in an attempt to treat the intractable fecal incontinence associated with spina bifida, a new and highly successful option became available (Malone et al, 1990). Koyle subsequently introduced the technique in North America in 1991 (Koyle et al, 1995). The concept behind this procedure is elegant and simple, which is to provide access to the colon (often at the level of the cecum) to allow regular emptying by means of antegrade instillation of fluid (so-called bowel "washout") (Fig. 144-15).

In essence, the MACE combines three well-recognized surgical principles familiar to pediatric urologists and surgeons: (1) complete colonic emptying can achieve bowel continence, (2) antegrade colonic emptying is feasible, and (3) the Mitrofanoff principle of continent cutaneous access to the bladder or bowel is highly successful and reproducible. Based on these, continent intermittent catheter access to the colon for the administration of antegrade enemas while the patient sits on the toilet produces colonic emptying and fecal continence. Success with this approach has been reported in numerous series, and it is now a procedure commonly practiced around the world (Squire et al, 1993; Griffiths and Malone, 1995; Koyle et al, 1995; Malone, 1995; Dick et al, 1996; Gerharz et al, 1997a; Schell et al, 1997; Peeraully et al, 2014).

The initial series described excising the appendix on its pedicle and then reimplanting it into the teniae of the cecum, as popularized with the Penn pouch continent urinary reservoir. Modifications have progressed to point of leaving the appendix in situ and retroverting it so that the serosa of the colon can be imbricated around it in an antirefluxing fashion, which can be achieved in an open, laparoscopic, or robotic-assisted fashion (Fig. 144-16).

Patient Selection and Preparation

For those children in whom conservative measures fail, retrograde enema compliance becomes an issue, and in those who experience successful bowel management through rectal enemas but desire or require a more convenient means of administration, surgical MACE might be considered an option. Although fecal continence is comparable whether enemas are administered rectally versus antegrade (Matsuno et al, 2010), procedural independence is often optimal for patients performing antegrade enemas. As such, the MACE procedure should be seen as an option that allows patient independence and avoids rectal instrumentation. The underlying

diagnosis is important as it influences the success rate. Other issues that might be considered include the presence, length, and quality of the appendix, the need and timing of urinary tract reconstruction, patient age and potential intellectual capacity, as well as dexterity, ambulatory status, and body habitus.

Patients with a neuropathic bowel and anorectal malformations seem to fare better than those with chronic idiopathic constipation (Curry et al, 1998). Nevertheless, with increasing experience modest success rates appear to improve (Curry et al, 1999; Kokoska et al, 2001). Age at operation is also important, with failures more commonly seen in younger patients irrespective of the diagnosis (Curry et al, 1998). This may reflect the inability of young children to sit on a toilet for up to 1 hour before emptying is complete or the lack of drive to achieve continence (as seen in older children because of school and peer pressure). Favorable outcomes appear to decrease again after puberty (Gerharz et al, 1997b; Christison-Lagay et al, 2010). This may reflect the impact of changes in body habitus associated with transferring issues in those with neurologic conditions, combined attempts at independence with less caregiver support, and compliance issues with the washout regimen.

Similar to any other catheterizing protocol, ensuring understanding and reinforcing information to the patient and to their caregivers are essential. The importance of ongoing detailed counseling and continued support cannot be overemphasized, both preoperatively and postoperatively (ideally provided by a well-trained dedicated member of the team, such as a nurse practitioner). These are essential to ensure adequate and continued motivation, without which the procedure is set for failure. The ideal patient for a MACE procedure should be between the ages of 5 and 12 years, have a diagnosis of neuropathic bowel, anorectal malformation, or Hirschsprung disease, be well motivated with a dedicated family, and have tried and failed all conservative measures.

Operative Technique

Although preoperative bowel preparation might facilitate the initiation of postoperative enemas, an aggressive cleanout is not necessary for the purpose of performing the procedure. Appropriate prophylactic antibiotics are always administered perioperatively, and these might be adjusted based on any concurrent urinary tract reconstruction. In most instances where coincidental urinary tract surgery is to be performed, a lower midline or Pfannenstiel incision is selected, depending on the patient's body habitus, scars from previous surgeries, and surgeon preference. Laparoscopy allows for identification of the appendix and mobilization of the colon, being particularly useful when the right colon is located high in the abdomen, close to the liver (Fig. 144-17). In such cases (often spina bifida patients with previous abdominal incisions and ventriculoperitoneal shunts), a large incision is avoided. In addition, the presence and status of the appendix itself can be confirmed. If only a MACE channel is to be performed, a pure laparoscopic or robotic approach, or an open appendectomy incision, can be used depending on the individual situation and the surgeon's experience and comfort.

In most descriptions of the ACE procedure an "antireflux" valve mechanism is fashioned to prevent leakage of bowel contents via the cutaneous stoma. Because the tendency is to maintain the appendix in situ, this is achieved by wrapping it with the cecal wall, as in the adaptation by Koyle that follows the principle of the Nissen fundoplication (Koyle et al, 1995). This can be performed in a minimally invasive way (Webb et al, 1997; Nanigian and Kurzrock, 2008; Lawal et al, 2011). To reduce the risk of compromising blood supply to the appendix, its mesentery is fenestrated to allow the passage of sutures and tissue without entrapping the vessels (Fig. 144-18). The colon can also be sutured to the posterior aspect of the anterior abdominal wall to ensure that the catheterizable conduit is not lying free in the peritoneal cavity, preventing kinking and difficulties with catheterization. It has been suggested that it is not necessary to construct an antireflux mechanism, and some have advocated avoiding this step and simply mobilizing the appendiceal-cecal unit to the abdominal stoma site, which is a procedure that

Figure 144-17. Diagnostic laparoscopy as the initial step to laparoscopic or laparoscopic-assisted Malone antegrade continence enema procedure. Presence, quality, and location of the appendix can be easily determined. Note location of cecum and appendix (arrow) close to the liver in a child with spinal dysraphism.

Figure 144-18. Fenestration of the appendix mesentery during laparoscopic Malone antegrade continence enema procedure, allowing passage of suture and creation of a cecal wrap without compromise of the blood supply (arrow). a, appendix; c, cecum.

is amenable to a purely laparoscopic or robotic-assisted approach (the so-called laparoscopic antegrade continence enema) (Webb et al, 1997; Thakre et al, 2008) (Fig. 144-19). Thus far, data appear to support no increase in stomal bowel incontinence based on retrospective reviews comparing MACE with and without cecal wrap (Koivusalo et al, 2006; Nanigian and Kurzrock, 2008).

If the patient requires synchronous bladder reconstruction, simultaneous MACE and Mitrofanoff urinary diversion offer patients the chance for complete dual fecal and urinary continence (Roberts et al, 1995; Wedderburn et al, 2001; Casale et al, 2006). The technique needs to be modified if both MACE and

appendicovesicostomy procedures are being considered. If the appendix is long enough and the vascular anatomy is suitable, it is possible to split the appendix (Fig. 144-20). If the appendix is not suitable to be split or is absent, alternative options must be considered. In these cases tubularized colon flaps (Fig. 144-21) or cecal extension of the appendiceal stump with a surgical stapler (Fig. 144-22) can be performed with relative ease, achieving good results with acceptable complication rates (Kiely et al, 1994; Herndon et al, 2005). The Monti-Yang procedure can also be employed as an alternative conduit (Monti et al, 1997) following the Mitrofanoff flap valve principle to implant in the bowel wall.

Figure 144-19. Laparoscopic-assisted cecostomy tube (C-tube) takedown and creation of Malone antegrade continence enema channel with appendix. Open imbrication through C-tube scar allows creation of “antireflux” mechanism. Note tip of appendix delivered through camera port at umbilicus (arrow).

Some advocate this option as the procedure of choice when the appendix is not available (Sugerman et al, 1998), and it can be particularly advantageous in very obese patients, as the use of a spiral or two segments of bowel will produce a conduit that is long enough for virtually all patients.

Another option worthy of consideration is the use of either a cecostomy tube (C-tube) or cecal button. Since the description by Chait and coworkers (1997a, 1997b), the technique for percutaneous placement of a cecal tube that can be regularly exchanged as a permanent, low-profile cecal button (similar to a gastrostomy button) has been refined. The C-tube option is favored when it is known that the appendix is absent (i.e., post-appendectomy), when the patient refuses to perform intermittent bowel

Figure 144-20. Long appendix with robust blood supply, amenable to split for simultaneous Malone antegrade continence enema channel and appendicovesicostomy.

Figure 144-21. Creation of access with a colon flap (A), tubularized and subsequently imbricated (B). This is suitable for catheterization for flushes to the left or right colon. Note flap tubularization over catheter (arrow).

catheterization, for patients who develop stomal complications such as stenosis (as an alternative to revision of the MACE channel), as a temporary therapeutic challenge to determine response to antegrade enemas or to determine whether the ideal placement of a permanent MACE should be in the right or left colon, and as a permanent option in cases where a nonoperative access is favored. Long-term outcomes reported by Chait and coworkers (1997a), who performed the procedure percutaneously under fluoroscopic guidance, show successful placement in a large number of children with satisfactory outcomes, certainly similar to other approaches (Chait et al, 2003). The tube can also be placed open or under laparoscopic guidance at the time of concomitant appendicovesicostomy (Lorenzo et al, 2007). The main drawback is that the tube entry site can become unsightly, with granulation tissue and occasional fecal leakage (Fig. 144-23). In these cases patients may opt for subsequent formal conversion to a bowel-based MACE, either laparoscopic or open (Fig. 144-24). Regardless, the tube or button can always be converted to a formal ACE with time, thus providing a reasonable initial option and a bailout in complicated cases.

A problem occasionally encountered, particularly in children and adolescents with severe constipation and a redundant colon, is the length of time needed for the washout to work. This issue

can lead to frustration, failure, and abandonment of the irrigations (Griffiths and Malone, 1995). In an attempt to rectify this problem, some have advocated placing the conduit in the left colon, rather than in the cecum. By doing so, the length of bowel that has to be washed through is reduced and, theoretically, so is the time needed for successful enema completion. Results using this approach have been encouraging, with similar outcomes and complication rates compared to traditional MACE (Liloku et al, 2002; Churchill et al, 2003; Meyer et al, 2008; Sinha et al, 2008; Blackburn et al, 2012), yet with less enema fluid requirements and shorter transit times (Sinha et al, 2008). A left MACE should be considered strongly in patients suffering from severe constipation. The decision between left or right access might be a difficult one, and it can be settled by temporarily placing a cecostomy or percutaneous colostomy tube. If equivalent or better on the right, then the *in situ* appendix is the simpler option.

The Enema Regimen

Although protocols differ, the first enema is commonly administered via the indwelling catheter or percutaneously placed tube following a progressive irrigation protocol that is initiated after the postoperative ileus resolves. Considering individual patient needs

Figure 144-22. Technique for cecal elongation of appendiceal stump with a surgical stapler effectively lengthening the channel, which is subsequently imbricated to prevent leakage. A, distal segment of appendix preserved for appendicovesicostomy; EC, elongated cecum; S, appendiceal stump.

Figure 144-23. Granulation tissue (black arrows) and leakage (white arrow) around cecostomy tube. Unsightly appearance and soiling can occur with time, which can lead to removal or conversion to a Malone antegrade continence enema channel.

and variable responses, there is much trial and error involved. One of the most important points, especially in the early weeks and months after surgery, is to advise patients not to expect immediate success, because early disappointment can lead to frustration and failure. In fact many children might not achieve a steady state or a reliable enema routine for a period of up to 6 months (Curry et al, 1998). Patients may also experience a degree of rectal leakage within the first few hours after the washout, but this does not appear to be a long-term problem. Although the washout regimen is being established outside the hospital, it is vital to maintain regular contact with the nurse specialist who helps manage the process.

Enema protocols differ among centers, and patients and families will frequently modify them to suit their own particular needs. Initially, daily washouts with 20 cc/kg of solution are encouraged, but after the patient is comfortable with the process and a routine has been established he or she may attempt to decrease frequency to alternate days. The time of day that the enema is administered is patient dependent, although most families prefer to administer the enema during the early evening hours after dinner. This time is chosen to allow a sufficient interval to achieve the desired result before bedtime. Rarely, others learn that twice-daily cleanouts are necessary and they adjust their frequency accordingly. Washout times range between 30 and 60 minutes. Because patients must sit on the toilet for a long period, buttock pressure sores may develop, and this is a complication that can be minimized with the use of padded toilet seats. Purges can be performed with a large volume of tap water (Koyle et al, 1995; Yerkes et al, 2001) or saltwater, with the judicious mix of additives such as glycerin, bisacodyl, phosphate, magnesium citrate, mineral oil, or PEG. Although uncommon, and depending on the solution used, water intoxication and/or electrolyte abnormalities may occur (Hunter et al, 1993; Schreiber and Stone, 1999). Changes and experimentation should only be performed under supervision to minimize this risk. After a steady state is achieved, there is little benefit from dramatically interfering or modifying the regimen.

Several difficulties can be experienced during enema infusion. The most common problem is pain or discomfort during instillation (Curry et al, 1998). In the majority of patients, this is a transient phenomenon that subsides during the first 3 months. Persistence beyond this time can contribute to discontinuation. Warming the solution, lowering additive concentration, reducing the rate of the infusion, using an antispasmodic before administering the enema, or using a licorice root solution can be attempted in these cases. It is always important to assure that the pain is not a result of distal fecal impaction (Fig. 144-25), which can occur despite regular washouts. These patients might require occasional retrograde cleanouts or might be candidates for repositioning the location of the access channel in the colon (cecum vs. right colon) (Liloku et al, 2002; Churchill et al, 2003).

Surgical Outcomes

In a survey of 300 ACE procedures performed by members of the British Association of Paediatric Surgeons, Curry and coworkers (1999) reported that success rates were dependent on the original diagnosis (Table 144-1). This large national series reported an overall full and partial success rate of 79%, with complication rates that were lower than in earlier historical series. In particular, stomal stenosis rates were reduced to 30%.

Standardized tools have been used to reflect improvements in quality of life (Shankar et al, 1998), self-esteem, psychosocial function (Aksnes et al, 2002), and fecal incontinence-related and constipation-related quality of life (including anxiety and family worry) (Ok and Kurzrock, 2011). Nonvalidated questionnaires have shown high satisfaction rates, with a majority of respondents recommending the procedure to others who have intractable defecation disorders (Hoekstra et al, 2011).

For patients undergoing synchronous bladder reconstruction and ACE procedures, a high percentage of fecal and urinary continence should be expected, with variable complication rates (Kajbafzadeh and Chubak, 2001; Wedderburn et al, 2001) and no

Figure 144-25. Presence of a large amount of fecal material in the distal colon and rectum (white arrows). This patient became impacted while doing infrequent antegrade enemas through a cecostomy access (black arrow). Attempts at clearing this fecal load with antegrade flushes only led to abdominal pain, lack of tolerance, and poor response. Improvement was achieved with disimpaction and retrograde enemas followed by diligent, regular antegrade flushes to achieve complete washout.

TABLE 144-1 Malone Antegrade Continence Enema Procedure Success and Failure* Based on Underlying Condition

DIAGNOSIS	FULL SUCCESS (%)	PARTIAL SUCCESS (%)	FAILURE (%)
Spinal bifida	63	21	26
Anorectal malformation	72	17	11
Hirschsprung disease	82	9	9
Idiopathic constipation	52	10	38
Other	44	25	31

*Surgical results have been classified as follows:
Full success: totally clean or minor rectal leakage on the night of washout.
Partial success: clean but significant rectal leakage, occasional major leak, still wearing protection, but improvement perceived by the parent or child.
Failure: regular soiling or constipation persists, no perceived improvement, and the irrigations are abandoned.

adverse impact compared to patients undergoing staged reconstruction (Casale et al, 2006). Stomal complications and difficulty catheterizing the conduits remain the most important postoperative problems (Barqawi et al, 2004). For example, Curry and coworkers (1998) reported an incidence of 55% for stomal complications. Ransley’s VQZ flap has been advocated as a technique to reduce the incidence of stenosis when the MACE is directed to a position other

Figure 144-26. Water-soluble contrast study through catheter placed in Malone antegrade continence enema channel (white arrows) to evaluate possible perforation (black arrow).

KEY POINTS: SURGICAL MANAGEMENT

- Surgical management of defecation disorders has been revolutionized with the concept of antegrade enemas, delivered through a catheterizable channel (MACE) or a C-tube. This enables the patient to evacuate the colon at regular intervals, avoiding impaction and reducing fecal incontinence.
- Patient selection is critical, and candidates should have failed maximal conventional measures before proceeding to invasive options.
- Although individual variations are expected, patients commonly perform washouts on a regular basis (daily or every other day) to achieve continence.
- Concurrent reconstruction of the gastrointestinal and genitourinary tract is feasible in most cases, with adaptations to fashion access to the bladder and bowel using available bowel segments.
- Surgical options include open, laparoscopic, robotic-assisted, and percutaneous techniques.

than the umbilicus (Malone et al, 1998; McAndrew and Malone, 2002; Landau et al, 2008). Conduit perforation and intraperitoneal enema instillation occurs rarely (3.7% during a 13-year period), but it can result in significant morbidity and the need for emergency surgical exploration (Defoor et al, 2005). If suspected, a contrast study through the channel may help establish the diagnosis (Fig. 144-26).

The “Functional” Urinary Tract

Patient Evaluation

Patient Preparation

Antireflux

Bladder Neck Reconstruction

Augmentation Cystoplasty

Continent Urinary Diversion

Summary

Although children with anomalies affecting the bladder and outlet are managed with a primary goal of minimizing the need for operative intervention, the basic functions of a “normal” lower urinary tract—to protect renal function, avoid urinary tract infection, and eventually provide urinary continence—must be achieved. Surgical reconstruction remains an important and effective tool for some children. When reconstruction is considered, it is imperative that the patient be thoroughly evaluated. Each child is unique, and their particular pathophysiology must be understood so that surgical techniques available may be used thoughtfully to optimize results while minimizing morbidity.

The scope of this chapter is large. Augmentation cystoplasty is reviewed in detail. In few areas of urology have intestinal segments been used as extensively. Complex patients with bladder dysfunction may also have bladder neck and external sphincteric problems, and this chapter covers techniques that increase bladder neck and external urinary sphincter resistance in the pediatric population. Perhaps the single most important contribution affecting lower urinary tract reconstruction was the introduction of clean intermittent catheterization (CIC) by [Lapides and colleagues \(1972, 1976\)](#) based on the work of [Guttmann and Frankel \(1966\)](#). Because many pediatric patients with bladder and sphincteric dysfunction will not void adequately after reconstruction, creation of a reliable means to easily catheterize may be essential; ways to do so are presented, along with related results in children.

Most pediatric lower tract reconstructive procedures are undertaken primarily to correct hostility in the native lower urinary tract unresponsive to medical management. Children with bladder and sphincteric dysfunction are among the most complex seen in pediatric urology, and those with spina bifida make up the majority of patients requiring this type of surgical intervention. The results discussed herein will therefore focus on the neurogenic population. Children with diagnoses such as exstrophy, persistent cloaca and urogenital sinus, posterior urethral valves, bilateral single ectopic ureters, and prune-belly syndrome may undergo similar reconstruction.

The most important factor influencing the outcome of urinary tract reconstruction in children is the commitment of the patient and family to achieving good care. Determining that commitment may at times be difficult, but its importance should not be underestimated.

THE “FUNCTIONAL” URINARY TRACT

Bladder physiology can be characterized in two dynamic phases, passive and active. During the passive storage phase, the bladder

functions as a reservoir allowing for urine to be stored at low pressure without leakage. In the active voiding phase, the bladder contracts and efficiently eliminates urine.

Basic Bladder Function

Passive: Storage

Urinary storage requires a reservoir that is compliant and of age-appropriate capacity. Age-based capacity may be estimated using formulas proposed by Koff (volume in milliliters = $30[\text{age in years} + 2]$) or Kaefer and colleagues (volume in milliliters = $32[2 \times \text{age in years} + 2]$ for children younger than 2 years, and volume in milliliters = $30[\text{age in years} + 2 + 6]$ for children older than 2 years) ([Koff, 1983](#); [Kaefer et al, 1997c](#)). Compliance is defined as the change in bladder volume divided by the change in pressure. Normally the bladder is a highly compliant vesicle in that it will accommodate an increasing volume of urine without a corresponding increase in intravesical pressure. Multiple factors contribute to this property. Initially the bladder is in a collapsed state, which allows for the storage of urine at low pressure by simple unfolding. As it expands, detrusor properties of elasticity and viscoelasticity engage. Elasticity allows the detrusor muscle to stretch without an increase in tension until it reaches a critical volume greater than the expected bladder capacity. The viscoelastic property allows for a subtle continuous pressure change during bladder filling. This small rise in pressure is balanced by a corresponding rapid pressure decay ([Zinner et al, 1976](#); [Wagg and Fry, 1999](#)). With slow natural bladder filling there is no net change in bladder pressure until capacity is reached. The viscoelastic bladder property is defined as stress relaxation and can be overcome when the rate of bladder filling exceeds normal parameters ([Mundy, 1984](#); [Finkbeiner, 1999](#)). This artifact of testing is often noted when urodynamic assessment is performed at an excessive filling rate for the child's age or size ([Joseph, 1992](#)). Properties of elasticity and viscoelasticity will eventually be overcome in every child; at that point, the bladder pressure rapidly rises. Favorable dynamics for appropriate urine storage include a thin bladder wall with an appropriate composition of muscle and collagen allowing for expression of normal elastic and viscoelastic properties. Factors adversely affecting normal compliance include detrusor hypertrophy, fibrosis, outlet obstruction, and recurrent urinary infections ([Mundy, 1984](#); [Joseph, 1994](#)).

Continence during urinary storage requires a closed bladder neck and external urinary sphincter. Fixed outlet obstruction, neurogenic dysfunction, and chronic inflammation can affect passive parameters, resulting in resting bladder hostility and clinical

manifestations of poor compliance, upper tract deterioration, and incontinence (Brading, 1997).

Active: Voiding

Under normal conditions the active phase of voiding requires the bladder to contract after descent of the bladder neck (Morrison, 1997). Reflexive opening of the bladder neck and sequential relaxation of the external urinary sphincter allow for low pressure balanced voiding and complete elimination of urine. Again, obstruction, neurogenic dysfunction, and chronic infection can cause physiologic changes preventing coordinated function of the detrusor, bladder neck, and external sphincter defined as dyssynergy (Mundy et al, 1985). A poorly functioning external sphincter from denervation fibrosis may also prevent appropriate relaxation, causing elevated voiding pressure against a fixed outlet. Finally, detrusor pathophysiology may prevent a sustained, coordinated bladder contraction and full elimination of all urine.

Dysfunction

Upper Urinary Tract

It is critical to understand the dynamics of the entire urinary tract before any major reconstructive procedure. In the presence of hydronephrosis, upper tract obstruction must be excluded. Upper tract obstruction may be secondary to severe, long-standing bladder hostility involving poor bladder compliance and emptying. Nuclear renography with a urethral catheter may be useful to rule out a primary upper tract obstruction. Upper tract obstruction, if present, should be corrected at the time of bladder and sphincter reconstruction.

Vesicoureteral reflux in the presence of bladder hostility may be primary or secondary, and differentiating the two may be difficult. If reflux was not present during earlier evaluation, new onset is likely secondary to bladder hostility. Reflux in children with neurogenic dysfunction is often secondary in nature. Previous work has suggested that reflux secondary to bladder hostility may not need surgical correction if the bladder is adequately managed. Neurogenic bladder requiring augmentation in children who did not undergo reimplantation for secondary reflux resolved with augmentation alone (Nasrallah and Aliabadi, 1991; Morioka et al, 1998; López Pereira et al, 2001; Soylet et al, 2004; Juhasz et al, 2008). It is interesting to speculate whether reflux is even a significant problem if a large, compliant bladder is achieved (Soylet et al, 2004). Bacteria may ascend with or without reflux after reconstruction, and certain forms of continent diversion have not shown an increased risk of pyelonephritis in the absence of any antireflux mechanism when compliance is adequate (Gonzalez and Reinburg, 1987; Helal et al, 1993; Pantuck et al, 2000). We agree that most secondary reflux will likely resolve with adequate reconstruction of the bladder but will correct high-grade reflux if present. Caution must be taken when considering the treatment of chronically dilated and scarred ureters. Correcting reflux in that setting is appropriate but can result in obstruction if overly aggressive tapering or tunneling is performed (Hendren, 1998).

Dysfunction in the upper urinary tract usually manifests with hydronephrosis, pyelonephritis, or impairment of renal function. When such problems are present in patients with lower tract dysfunction, thoughtful evaluation and treatment are necessary. All problems should be addressed before and at the time of reconstructive surgery to achieve the best result.

Bladder Dysfunction

Bladder dysfunction is a composite of physiologic abnormalities, and it is helpful to assess each component of passive and active bladder function independently. **Elevated passive filling pressure becomes clinically pathogenic when a pressure greater than 40 cm H₂O is chronically reached** (McGuire et al, 1981; Wang et al, 1988; Weston et al, 1989). Pressures at this level sustained

over a period of time impair ureteral drainage that may result in pyelocalyceal changes, hydroureteronephrosis, and decreased glomerular filtration rate. In addition, persistent elevation in filling pressure can result in acquired vesicoureteral reflux (Sidi et al, 1986a; Cohen et al, 1990).

Pharmacologic management can play a role in decreasing filling pressure, particularly when overactive detrusor contractions are present. A combination of medications and intermittent catheterization have a positive impact, particularly in children with neurogenic dysfunction (Rink and Mitchell, 1984; Aslan and Kogan, 2002; Verpoorten and Buyse, 2008). When compliance is unaffected by medical management, augmentation cystoplasty may be required to improve the storage characteristics. After reconstruction, the likelihood of efficient detrusor contractions and effective emptying of the bladder is diminished. Intermittent catheterization should be taught and accepted by the patient and caretaker preoperatively. CIC allows the reconstructive surgeon to aggressively correct storage problems through augmentation. Spontaneous voiding, while a goal, is not imperative because CIC can be used for emptying.

Urinary incontinence is a prominent sign of bladder dysfunction. Continence requires outflow resistance generated by the bladder neck and external urinary sphincter. Outflow resistance must remain greater than bladder pressure during storage throughout normal daily activity. When outflow resistance is diminished because of an abnormal bladder neck and external urinary sphincter, incontinence often will occur. Pharmacologic management with α -adrenergic agents can enhance outflow resistance, but more commonly operative reconstruction is required.

When incontinence occurs during the filling phase because of poor outlet resistance, it is essential to evaluate not only the bladder neck and external urinary sphincter, but also detrusor characteristics. Clinical experience has shown that once appropriate resistance is achieved at the bladder neck through operative intervention, adverse detrusor characteristics may become unmasked and result in high pressure urinary storage or uninhibited contractions not previously documented (Bauer et al, 1986; Churchill et al, 1987; Dave and Salle, 2008). For that reason, provocative urodynamic assessment with occlusion of the bladder neck is important before any bladder neck reconstruction in an attempt to identify children who will be at risk.

Normal synergistic voiding occurs when the bladder neck descends, relaxes, and opens, followed by relaxation of the external urinary sphincter and subsequent detrusor contraction resulting in low pressure voiding. Dysfunctional voiding during this active bladder phase occurs as a result of uncoordinated activity of the bladder neck, external urinary sphincter, and detrusor. With such dyssynergy, high-pressure voiding results that chronically can negatively affect the bladder and upper urinary tract (Mundy et al, 1982; Bauer et al, 1984). A similar clinical situation occurs with a fixed, fibrotic external sphincter. Initial treatment involves pharmacologic management and CIC in an attempt to bypass the abnormal voiding mechanics.

Other Considerations

Renal function should be assessed in any patient undergoing bladder reconstruction, particularly if hydronephrosis or severe renal scarring is present. Demos (1962) and Koch and McDougal (1985) have demonstrated that urinary solutes, particularly chloride, are absorbed from urine in contact with the mucosa of small and large bowel. For patients with normal renal function, the kidneys are able to handle the reabsorbed load of chloride and acid without obvious difficulty. Patients with decreased renal function, however, may develop significant metabolic acidosis secondary to such reabsorption. If acidosis exists preoperatively, it will invariably worsen if urine is stored in small or large intestinal segments (Mitchell and Piser, 1987). The first component of renal function to deteriorate after obstruction or infection is concentrating ability. Patients with compromised function may generate enormous volumes of urine. **The bladder volume achieved through bladder reconstruction must accommodate the patient's urinary**

output for an acceptable period of time, usually 4 hours. Patients with renal failure or other medical problems may conversely develop oliguria. Low urinary output may affect an augmented bladder or bladder reservoir with greater collection and inspissation of mucus.

Abnormal function of other organ systems also influences the risk of bladder reconstruction using intestinal segments. Reabsorption of ammonia by large or small intestinal segments in contact with urine may be dangerous for patients with hepatic failure (McDougal, 1992a). Some medications excreted in urine may be reabsorbed by bowel mucosa (Savauagen and Dixey, 1969). Therefore, liver function tests and arterial blood gas studies may be appropriate. Careful history should be taken regarding the patient's preoperative bowel function; this is particularly true of patients who may have acquired or secondary gastrointestinal problems. Short gut syndrome is a concern among children with cloacal extrophy, prior bowel resections, or a history of significant radiation. A history of chronic diarrhea or fecal incontinence preoperatively should signal concern about use of the ileocecal valve in urinary reconstruction.

A critical factor to consider is the commitment of the patient and family. Urinary incontinence, at times, protects some patients from infection and upper tract deterioration. Effective storage can put the patient at risk for problems if emptying is not accomplished on a regular basis. All must be aware of the responsibility that goes along with bladder reconstruction and urinary continence.

The timing of surgical intervention varies dramatically among patients. It might be necessary to perform reconstruction early when the upper tracts and renal function are threatened. This situation may occur in the presence of high outflow resistance and poor bladder compliance. Although work has suggested that augmentation cystoplasty to correct bladder hostility may slow deterioration of renal function even when renal insufficiency resulting from secondary upper tract damage is already established (Ivancic et al, 2010), early intervention to prevent such damage is preferable. More commonly, reconstruction is undertaken later to achieve urinary continence. The age at which urinary incontinence, or the presence of a urinary stoma after temporary diversion, becomes socially unacceptable varies among patients and families.

It is beneficial for the patient and family to wait for bladder reconstruction until all needs of the child are identified. This is not always possible when intervening because of infection or hydronephrosis. When reconstruction is undertaken to achieve continence, it is most efficient to identify all reconstructive issues and address them with one operation. Urodynamic assessment is usually necessary to determine whether a procedure to increase outflow resistance is necessary in addition to bladder augmentation or replacement. Introducing CIC preoperatively is mandatory in that it allows the patient to demonstrate the ability and desire to continue on a regular basis. It is also helpful in determining whether a continent abdominal wall stoma may be required to improve the reliability of catheterization and increase the patient's independence. Likewise in the neurogenic population, it is advantageous to identify the child who may benefit from an antegrade colonic enema. It is certainly better for the patient and surgeon to address all of these issues at one time rather than with sequential procedures that may add morbidity.

PATIENT EVALUATION

Each patient should have upper tract imaging before bladder reconstruction; most will have had routine ultrasonography as part of their surveillance. **When hydronephrosis is present, imaging should be performed to assess for obstruction or vesicoureteral reflux.** Nuclear renography with a catheter in the bladder is usually adequate to rule out primary upper tract obstruction. Reflux should be excluded with an independent voiding study or as part of video urodynamics. In the presence of hydronephrosis, patients should have baseline levels of serum electrolytes, blood urea nitrogen (BUN), and serum creatinine obtained. Patients with elevation of

the serum creatinine or significant hydronephrosis benefit from nephrologic evaluation and a 24-hour urine collection for creatinine clearance and urine volume.

Special attention must be given to patients after prior urinary diversion. Permanent intestinal diversions in children are now typically confined to patients requiring cystectomy for cancer. Most urinary diversions performed today are temporary in nature. **The key to urinary undiversion is to understand the original pathology that led to diversion.**

Urodynamics

Bladder Dynamics: Capacity and Compliance

Urodynamic testing of the lower urinary tract plays an essential role when considering bladder reconstruction. Results in infants and children are reproducible but require meticulous attention to detail (Joseph, 1994). Several mechanical factors adversely influence urodynamic data, creating artifacts that, if not recognized, can have a negative impact on the validity of the evaluation. Testing is typically performed with transurethral catheter placement. The size of the catheter can influence the measured leak point pressure, voiding pressure, and ability to empty completely, particularly in infants and young boys (Dexter and Harpser, 1992). Suprapubic catheter placement circumvents this problem but is not practical in most cases. The testing medium and infusion rate can influence the results. Carbon dioxide is not as reliable as fluid infusion, particularly when evaluating bladder compliance and capacity. Most commonly, saline or iodinated contrast is used at body temperature to provide reproducible results (Joseph, 1993, 1996). End filling pressure, and therefore bladder compliance, can be dramatically affected by simply changing the filling rate (Joseph, 1992). Bauer (1979) suggested that the cystometrogram be performed at a fill rate of no greater than 10% of the predicted bladder capacity per minute.

Special nuances may be necessary after diversion by vesicostomy. Any bladder is likely to show small capacity in that setting. A repeated study after several days of bladder cycling by occlusion of the vesicostomy may be more predictive of bladder function; the bladder may respond to cycling quickly (McGuire, personal communication, 1996; Errando et al, 2005). Temporary occlusion of the ostomy with a gastrostomy button may be informative (de Badiola et al, 1995).

Sphincter Dynamics: Outflow Resistance

The bladder neck and external urinary sphincter work in synergy, but only one is required for maintenance of urinary continence. Neurogenic dysfunction often leads to abnormalities of the bladder neck and external urinary sphincter, resulting in diminished outlet resistance during storage and/or dyssynergic function with voiding. Monitoring of external urinary sphincter electrical activity is required for evaluation of coordinated voiding and dyssynergic detrusor sphincter activity. Perineal surface electrodes, abdominal wall sensors, anal plugs, vaginal monitors, electrical wires, and concentric needle electrodes have all been used for electromyography (Joseph, 1996). In children with neurogenic dysfunction, a concentric needle electrode or dual needle electrodes placed through a 25-gauge needle increase accuracy when measuring sphincter activity (Blaivas et al, 1977; Joseph, 1996).

The functional length of the external urinary sphincter also plays a role in outflow resistance, and its measurement can be undertaken with urethral pressure profilometry (UPP). Unfortunately, the short length and small diameter of the pediatric urethra makes this study technically challenging because the mechanical pulling device is not practical for pediatric use. To perform UPP, a constant infusion of testing medium at a rate of 2 mL/min using a continuous Harvard pump is required (Joseph, 1996), eliminating pressure wave artifacts noted with the standard roller ball infusion pumps. Hand withdrawal of the catheter is used, marking every 5 mm on the recording strip. With experience and a cooperative patient, reliable measurements can be obtained. There is limited value comparing

specific UPP results for a patient against standard nomograms; however, preoperative UPP for a given patient provides baseline information that can be beneficial when assessing the intraoperative and postoperative functional urethral length.

Some surgeons use leak point pressure to evaluate outflow resistance during passive filling and Valsalva. It should be recognized that the leak point pressure may be artifactually elevated by the urodynamics catheter in a small male urethra (Decter and Harpster, 1992). Work remains to determine how well such measurable parameters correlate. Khoury and associates (2008) suggest that the presence of bladder trabeculation often predicts that outlet resistance is adequate and that such patients are likely to do well with augmentation cystoplasty alone.

Bladder Emptying

The patient's ability to empty the bladder before reconstruction should be assessed carefully. Parameters influencing bladder emptying include synergistic relaxation of the external sphincter on electromyography, urinary flow rates, and residual postvoid urine. Neurologically intact patients able to empty their bladder well preoperatively are much more likely to do so after reconstruction than are patients with neurogenic dysfunction. **No test ensures that a patient will be able to void spontaneously and empty well after bladder augmentation or other reconstruction.** Therefore all patients must be prepared to perform CIC postoperatively. The native urethra should be examined for the ease of catheterization. Ideally, the patient should learn CIC and practice it preoperatively until the patient, family, and surgeon are comfortable that catheterization can and will be done reliably. Physical and psychosocial limitations of the patient must be considered with regard to the ability to self-catheterize and perform independent care. **Failure to catheterize and empty reliably after bladder reconstruction may result in upper tract deterioration, urinary tract infection, or bladder perforation despite a technically perfect operation.** Most patients who may catheterize per native urethra or an abdominal wall stoma will overwhelmingly prefer the latter (Horowitz et al, 1995).

PATIENT PREPARATION

Bladder and sphincter reconstructive procedures remain challenging. The patient's general status should be optimized to afford the best chance to achieve a good result with the least risk of morbidity. General nutritional and hydration status should be determined and corrected, if necessary, before surgery. Coexisting medical problems, particularly cardiac and pulmonary issues, should be well managed preoperatively.

Bowel Preparation

Each patient undergoes preoperative bowel preparation to minimize the potential risk of surgery if the use of any bowel is required. Even when ureterocystoplasty or other alternatives are planned, intraoperative findings may dictate the need for use of a bowel segment. Two days of a clear liquid diet before bowel preparation aid in clearing of solid stool. The patient should then undergo full mechanical bowel preparation the day before surgery. Such bowel preparations have usually been done in the hospital (O'Donnell, 2007); however, recent trends find this changing to an outpatient setting. Major reconstructive procedures often require many hours of operative time with large fluid shifts. It is critical that the patient be well hydrated at the time of surgery even if it necessitates the use of intravenous fluids during the preoperative day. The use of oral antibiotics in bowel preparation, once dogma, is now a matter of personal preference. Special attention must be paid to the bowel preparation of patients with neurogenic dysfunction. Most of these patients have chronic constipation, and effective bowel cleansing can be difficult in such patients. Several days of oral cathartics at home may be helpful before formal preparation. Children with

renal insufficiency should be observed carefully during bowel preparation for dehydration and electrolyte disturbances.

Theoretically, gastric contents are sterile, and administration of parenteral antibiotics or a routine bowel preparation is not necessary before gastrocystoplasty. Gundeti and associates (2006) suggested that routine bowel preparation may not be necessary before ileocystoplasty in children.

Urine Culture

All patients should have a urine culture performed several days before bladder reconstruction. Any patient with a positive preoperative urine culture should undergo treatment with either oral or intravesical antibiotics and have a second culture documenting sterile urine before the procedure. Many pediatric patients undergoing augmentation cystoplasty have spina bifida and a ventriculoperitoneal shunt. With a negative urine culture and good bowel preparation, the incidence of shunt infection or problems should be very low (Yerkes et al, 2001; Hayashi et al, 2008).

Cystoscopy

Preoperative cystoscopy may be the final step in evaluating the native bladder, outflow, or ureteral orifices in pediatric patients. Endoscopy, if done, should be performed immediately before bladder reconstruction under the same anesthetic. Based on history, an occasional patient may warrant endoscopic or radiographic gastrointestinal evaluation preoperatively.

KEY POINTS: EVALUATION AND PREPARATION

- Evaluation for renal function, upper tract obstruction, and vesicoureteral reflux should be performed if hydronephrosis is present, although most such changes are secondary to the bladder dysfunction.
- Careful urodynamic evaluation is critical to understand all problems that may contribute to the dysfunction.
- The patient will likely require CIC to empty after reconstruction and must be capable of performing it on a reliable basis.
- Commitment of the patient and family is essential.
- Basic preoperative preparation includes sterile urine and thorough bowel cleansing.

ANTIREFLUX

Ureteral reimplantation into bladder, whether the ureter is dilated or not, is a standard procedure familiar to all pediatric urologists and reconstructive surgeons. The long-term success rate is good and complications rare. Such reimplantation is certainly preferable and usually possible during lower tract reconstruction. Special attention must be given to chronically scarred, short ureters sometimes found after urinary diversion. In Henden's extensive experience with urinary undiversion (1998), most complications were related to those ureters.

Transureteroureterostomy and Single Ureteral Reimplant

Occasionally, the urinary bladder is so small that it is inadequate for bilateral reimplantation, and alternatives must be considered. It is preferable to reimplant both ureters separately, although if the native urinary bladder is small and adequate for only a single ureteral tunnel, transureteroureterostomy (TUU) and a single reimplant may be helpful (Fig. 145-1). Typically, the better ureter should be implanted into the bladder. The crossing ureter should be mobilized to swing gently across the abdomen to the recipient side in a smooth course without tension. It should be carefully mobilized with all of its adventitia and as much periureteral tissue

Figure 145-1. Technique for transureteroureterostomy. AO, aorta; inf. mes. art., inferior mesenteric artery. (Courtesy W. Hardy Hendren.)

as possible to preserve blood supply. Care must be taken not to angulate the crossing ureter immediately beneath the inferior mesenteric artery. The crossing ureter is widely anastomosed to the posteromedial aspect of the recipient ureter. The recipient is not mobilized or brought medially to meet the end of the other ureter. TUU when fashioned appropriately is successful and carries minimal risk for leakage or obstruction (Hodges, et al, 1963; Hendren and Hensle, 1980; Noble et al, 1997; Mure et al, 2000; Iwaszko et al, 2010). A history of previous calculi remains a relative contraindication to TUU.

The manner in which the bladder is opened may optimize its use for a single reimplant. Rather than incising the bladder in the anterior midline, a wide, anterior U-shaped incision based cephalad can be made. This potentially elongates the bladder as a posterior plate that can be brought to one side or the other to meet a single ureter. For ureteral reimplantation after such an incision, a psoas hitch of the bladder fixes the bladder in position for a long, straight ureteral tunnel. Incision of the bladder in this way may also be useful in placing a continent catheterizable stoma to the umbilicus.

Psoas Hitch

Fixation of the bladder to the psoas muscle allows for precise control of both the length and direction of a ureteral reimplant. A psoas hitch should prevent any angulation of the ureter with bladder filling. Such angulation may be particularly problematic or obstructive with a dilated and scarred ureter. The bladder should be secured to the psoas muscle and fascia using nonabsorbable sutures. Those sutures must not enter the bladder lumen or stones will occur. Broad, shallow purchases of the psoas muscle and fascia should be used to hold long term without trapping the sciatic nerve. The hitching sutures should not be tied so tightly that they cut through either bladder or psoas muscle. The contralateral bladder pedicle may be divided to increase bladder mobility and the length of the hitch on occasion. Although Hendren and Hensle (1980) suggested that the ureteral reimplant is more easily performed before the bladder hitch (Fig. 145-2), the steps should be performed

in whichever order allows each to be done precisely with good visualization.

Antireflux with Intestinal Segments

Necessity of ureteral reimplantation into an intestinal segment may occasionally determine the segment to be used for bladder augmentation or replacement. Long experience with ureterosigmoidostomy and colon conduit diversion has established an effective means of creating antireflux into a colonic segment; a flap valve mechanism can be created by tunneling the ureter beneath a tenia. Principles learned from ureterosigmoidostomy include a direct mucosal-to-mucosal anastomosis and a submucosal tunnel of adequate length. This technique has provided favorable long-term results since the 1950s (Nesbit, 1949; Goodwin et al, 1953; Leadbetter and Clarke, 1954) and is based on the initial work of Coffey (1911). Implantation may be done from within the reservoir or from without after the intestinal segment has been completely reconfigured and closed.

If a gastric segment is used for bladder augmentation or replacement, ureters may be reimplanted into the stomach in a manner remarkably similar to that used in the native bladder. The same principles for choosing the length of tunnel relative to the width of the ureter are used as with bladder. Creating an effective antireflux mechanism into an ileal segment is more difficult. The split nipple technique described by Griffith may prevent reflux at least at low reservoir pressure (Turner-Warwick and Ashken, 1967; Patil et al, 1976; Stone and MacDermott, 1989; Sagalowsky, 1995). A short longitudinal incision is made in the distal ureter, and the ureteral wall is turned back on itself. The nipple should be at least twice as long as the width of the ureter. The cuff is stabilized by suturing the ureter to itself. The adventitia of the ureter immediately proximal to the cuff is then approximated to the full thickness of the ileal wall at the hiatus so that the cuff protrudes into the lumen. Le Duc et al, (1987) described a technique in which the ureter is brought through a hiatus in the ileal wall. From that hiatus, the ileal mucosa is incised and the edges are mobilized so as to create a trough for the ureter. The spatulated ureter is laid into the trough and approximated to the mucosa at the distal end. The ileal mucosa is sutured to the lateral edges of the ureter and should eventually grow over it. Long-term results with these two techniques have been conflicting but in general have not proven as reliable as a tunneled uretero-colonic anastomosis in preventing reflux (Patil et al, 1976; Le Duc et al, 1987; Rowland, 1996; Bihrlé, 1997), with one exception (Lugagne et al, 1997). It is also possible to create an antirefluxing, serosally lined tunnel between two limbs of ileum as described by Abol-Enein and Ghoneim (1999; Soygur et al, 2005).

Reinforced nipple valves of ileum have been used extensively for antireflux with the Kock pouch (Skinner et al, 1989). After several modifications by Skinner, good long-term results have been achieved. His technique requires a relatively long segment of ileum and use of permanent staples. Attempts have been made to secure the nipple long term without staples or mesh (Hanna and Blois, 1987; Gosalbez and Gousse, 1998; Tsuchiya et al, 2004). Maintenance of the intussuscepted cuff is the key to a successful result. The same forces that compress the nipple to achieve antireflux or continence tend to evert or destabilize it. An ileal nipple valve may be particularly useful with short, dilated ureters; an isoperistaltic segment of ileum may be left with the nipple to replace a short ureter. The antireflux mechanism is based on the ileal segment and not the ureter. In some neobladders, an isoperistaltic limb of ileum is positioned between the reservoir and ureters to discourage reflux, at least at low pressures (Studer and Zingg, 1997).

KEY POINTS: ANTIREFLUX

- Ureteral reimplantation into native bladder is preferable when necessary; the initial bladder incision may facilitate such a procedure.
- An antireflux mechanism can be created with any bowel segment but is most challenging with ileum.

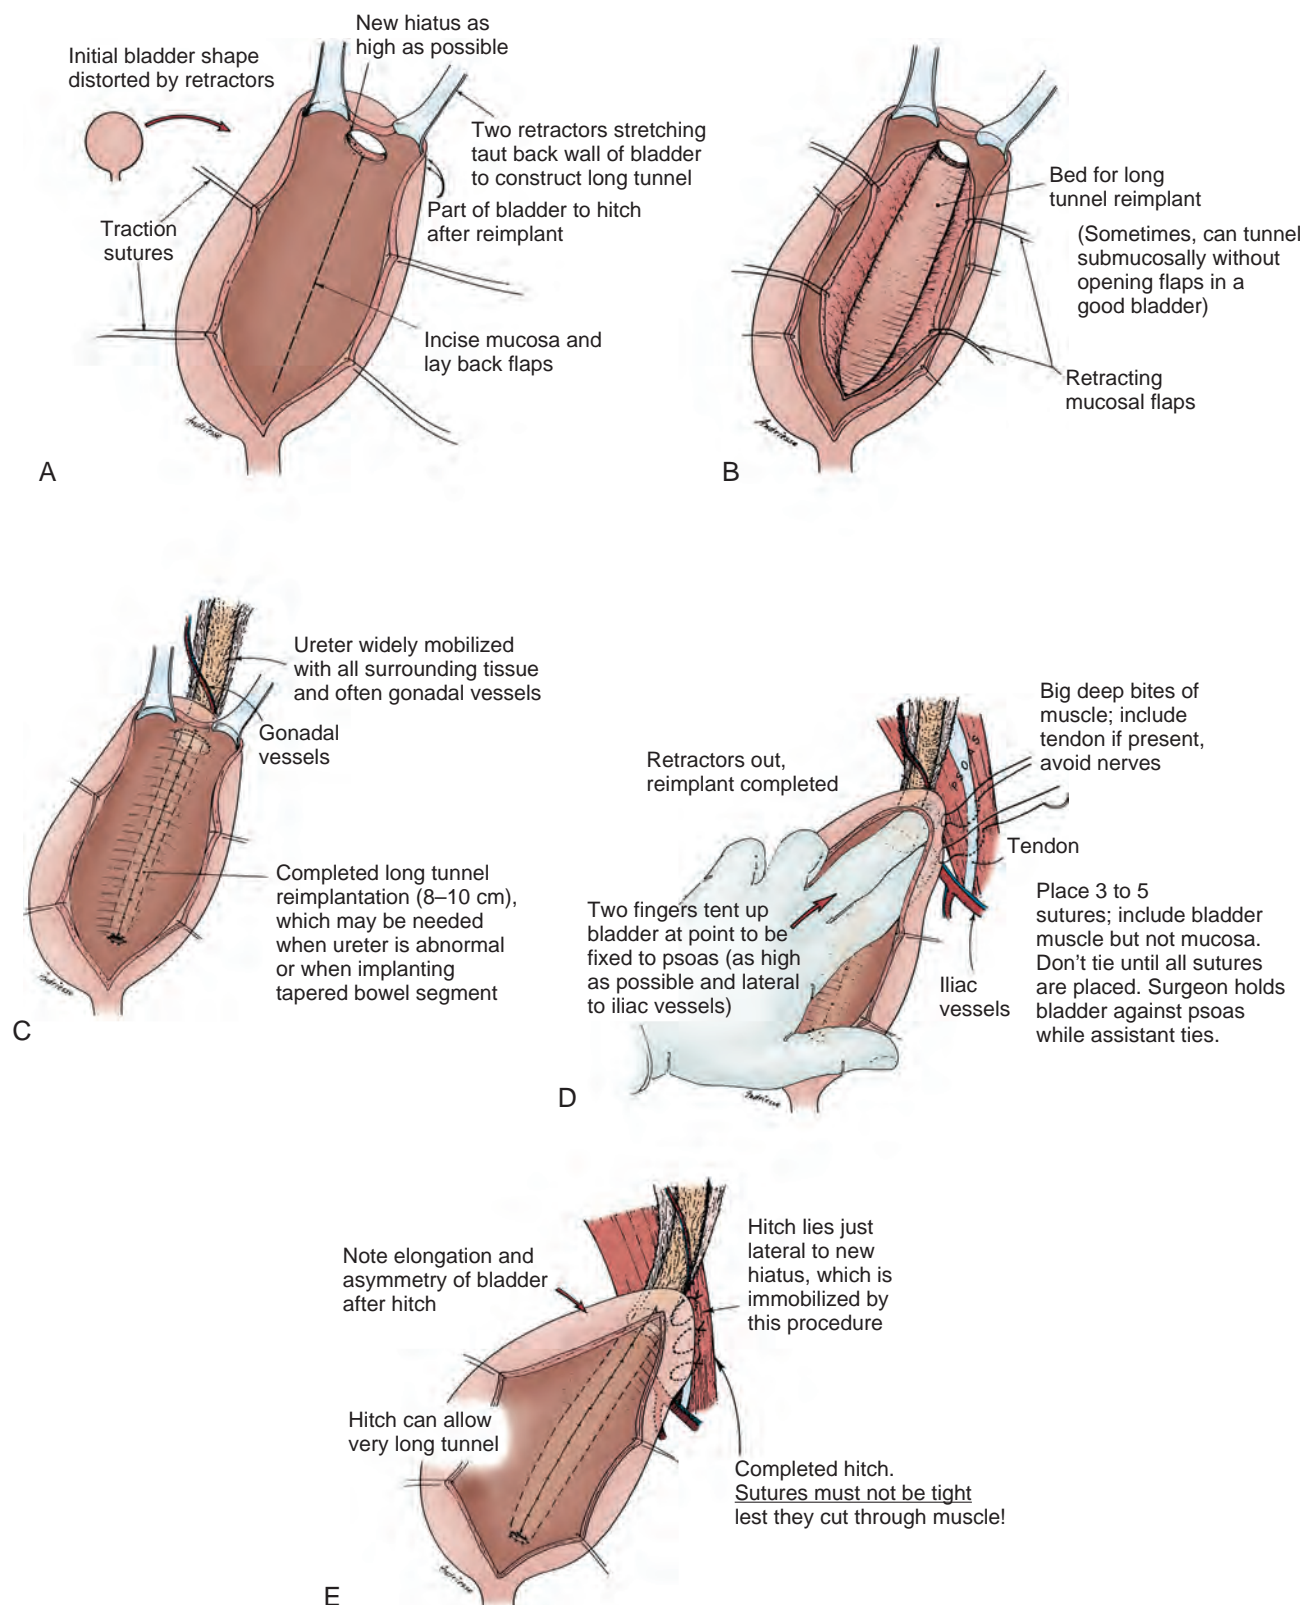

Figure 145-2. Technique for psoas hitch, which allows the construction of a long reimplantation tunnel and prevents angulation of the ureter or tapered bowel segment when the bladder fills. Monofilament nonabsorbable suture material is used to fix the bladder to psoas muscle. Care must be taken to avoid entering the bladder, which might cause stone formation on a suture. (Courtesy W. Hardy Hendren.)

BLADDER NECK RECONSTRUCTION

One of the greatest technical challenges facing the surgeon regarding bladder reconstruction is reliably providing adequate outflow resistance to achieve continence. The cause of bladder neck dysfunction may be neurogenic in origin or anatomic as noted with exstrophy, bilateral ectopic ureters, or ureteroceles. Each unique problem must be considered when addressing outlet resistance. Many operative techniques have been described for bladder neck reconstruction, indicating that no single option is best for all patients (Kryger et al, 2000; Cole et al, 2003; Lemelle et al, 2006). **It cannot be overstated that preoperative evaluation and thorough knowledge of the patient's specific physiologic limitations are required.**

The capability for a sustained bladder contraction to result in complete emptying by voiding or the absence of hyperreflexic contractions influences the technique selected for gaining outlet resistance. All operative techniques that create an increase in outlet resistance do so at the expense of detrusor contractility. For reasons not clearly defined, increasing outlet resistance can result in a noncompliant hostile detrusor environment (Bauer et al, 1986; Burbige et al, 1987; Churchill et al, 1987). Provocative cystometry may uncover only some patients at risk, and close postoperative observation is mandatory (Kronner et al, 1998b).

Multiple techniques are available to tighten the bladder neck and include creation of a flap valve mechanism, placement of artificial or autologous bulking agents, slings, and the artificial urinary sphincter (AUS). **The selected option is individualized to the patient's pathologic process, needs, goals, and desire for independence.**

An important consideration is the patient's ability to empty well before reconstruction and the likelihood that he or she will be able to do so afterward. Many of the repairs prohibit spontaneous voiding. Some patients with neurogenic dysfunction will require bladder augmentation and an increase in bladder outflow resistance, resulting in the need for CIC. Other diagnoses, especially when augmentation cystoplasty is not necessary, may allow for spontaneous voiding.

The following section covers operative techniques used to achieve urinary continence through bladder neck and external urinary sphincter reconstruction. Most of the results are based on experience in individuals with spinal dysraphism, but the techniques are used in children with other pathogenic conditions. All techniques have a learning curve that necessitates careful analysis of results and forthright reporting. An evidence-based review of operative bladder neck procedures found assessment of results to be limited by several factors, including the lack of a true, consistent definition of "success" and "continence," consideration of patients with and without concomitant bladder augmentation, and consideration of small patient populations with mixed pathologic conditions (Joseph et al, 2003).

Young-Dees-Leadbetter Repair

The Young-Dees-Leadbetter bladder neck reconstruction is one of the most recognized operative techniques to increase outlet resistance. The original Young procedure has evolved and remains of primary consideration when reconstructing the exstrophic bladder neck (Ferrer et al, 2001).

Technique

Young's initial description (1919) of excising a portion of the bladder neck and tightening the bladder neck over a silver probe was modified by Dees (1949), who extended the length of excised tissue through the trigone. Leadbetter (1964) followed by elevating the ureters off the trigone and placing them in a more cephalad position on the bladder floor. This allowed for tubularization of the trigone and enhanced lengthening of the urethra. A detailed description and illustrations are found in the chapter on bladder exstrophy.

Results

Reports of success with the Young-Dees-Leadbetter bladder neck reconstruction in children with neurogenic sphincter dysfunction are limited, not only in the number of patients but also in overall improvement. Tanagho (1981) and Leadbetter (1985) independently reviewed their long-term results and showed minimal success in individuals with neurogenic dysfunction. They speculated that the outcomes were the result of a lack of muscle tone and activity in the wrapped muscle related to the underlying neurogenic problem. Many patients in the early series did not undergo bladder augmentation, possibly compromising the continence achieved. Contrary to the results reported in exstrophy patients, most individuals with neurogenic deficiency of the bladder neck require bladder augmentation and intermittent catheterization. Sidi and colleagues (1987b) documented a 4-hour continence interval in 7 of 11 patients after such repair, although 10 required catheterization and nine augmentation. Five of the 7 needed a second surgery to achieve continence. This small series is one of the more recent showing long-term results of the Young-Dees-Leadbetter reconstruction in children with neurogenic dysfunction, as it has largely fallen out of favor. In an attempt to enhance the Young-Dees-Leadbetter procedure, Mitchell and Rink (1983) described the addition of external support and compression achieved through the placement of a silicone sheath around the reconstructed bladder neck. This was done to establish a plane for future placement of an artificial sphincter cuff, if necessary. The sheath improved the function of the repair by either increasing coaptation or maintaining the repair in a better anatomic position. Unfortunately, most of the thicker Silastic sheaths eventually eroded into the bladder or urethra (Kropp et al, 1993). Quimby and colleagues (1996) used a thinner Silastic sheath with interposed omentum and reported less risk of erosion. The authors noted improved continence and felt placement of an artificial sphincter cuff was easier when needed.

Donnahoo and colleagues (1999) reviewed one of the largest series of this repair used in neurogenic incontinence (38 children, 25 of whom were girls). A primary repair was performed in 24 children, a secondary procedure in 6, and a primary repair in conjunction with a silicone sheath in 8. Partial continence was achieved after the initial repair in 26 children (68%). All children with the silicone sheath were initially continent, but erosion occurred in 5. In addition, 35 (92%) of the children required augmentation cystoplasty in order to become continent without hostile detrusor characteristics. The authors found that although continence could be achieved with this technique, it was at the expense of augmentation cystoplasty and multiple procedures. Their results are similar to those reported by Cole and associates (2003).

Fascial Sling

Sling procedures were developed in an attempt to increase resistance at the bladder neck. Both artificial tissue and autologous fascia have been used. Continence is based on coaptation and elevation of the bladder neck that approximates opposing epithelial surfaces and increases outlet resistance greater above resting bladder pressure and the pressure reached during stressful activity or Valsalva behavior. With sling coaptation, the bladder neck remains fixed, and although a strong detrusor contraction can establish a voiding pressure leading to urinary flow, it rarely allows adequate bladder emptying in the face of anatomic or neurologic problems. The majority of pediatric patients who undergo a sling procedure must be prepared for CIC. The resistance achieved with bladder neck slings can potentially be overcome by overactive bladder contractions or elevated pressure caused by diminished bladder compliance. Therefore, simultaneous bladder augmentation has again been reported in 55% to 100% of patients who achieve urinary continence after a sling procedure (Bauer et al, 1989; Elder, 1990; Decter, 1993; Kakizaki et al, 1995; Perez et al, 1996a; Dik et al, 1999; Walker et al, 2000; Bugg and Joseph, 2003; Cole et al, 2003; Dik et al, 2003; Godbole and Mackinnon, 2004).

Only Snodgrass and colleagues have reported good results of bladder neck reconstruction without augmentation cystoplasty in these patients (Snodgrass et al, 2007, 2010; Snodgrass and Barber, 2010). However, long-term assessment from 2000 to 2014 of 109 patients from this group found that 70% required an additional continence procedure, 30% have required augmentation, 50% developed upper tract changes, and 20% developed chronic kidney disease (Grimsby et al, 2015). Alternatives to fascia, such as an expanded fluorocarbon polymer (Gore-Tex) have been used in a similar fashion, although early continence has not been maintained (Godbole and Mackinnon, 2004). Good early results have been noted with some biodegradable scaffolds (Colvert et al, 2002).

Technique

The bladder neck is exposed by clearing fatty tissue overlying the bladder neck and the lateral endopelvic fascia. An incision is made within the endopelvic fascia for approximately 2 cm. The junction between the bladder neck and proximal urethra can be identified by placing a transurethral catheter into the bladder and gently pulling down on the catheter to lodge the balloon at the bladder neck. Using blunt dissection, a plane between the posterior bladder neck and vagina in girls or rectal wall in boys is developed. The proper plane may be more easily developed from the cul-de-sac by dissecting behind the bladder and ureters from above (Lottmann et al, 1999; Badiola et al, 2000). If the landmarks are not easily defined, as in a secondary repair, the dissection becomes difficult. It may be appropriate to open the bladder to help prevent inadvertent dissection into the urethra or posterior structures. Dik and colleagues (2003) proposed use of a transvaginal approach, eliminating the need to open the bladder or dissect between the bladder neck and anterior vagina.

When fascial tissue is used, the technique is based on that described by McGuire and Lytton (1978) for stress urinary incontinence. Rectus abdominus fascia 1 cm in width and of an appropriate length is harvested. This fascia can be taken either in vertical or horizontal fashion depending on the initial skin incision. Fascia from other sites has been used in a similar fashion but requires a second incision. Cadaveric tissue or biodegradable scaffolds may also be used (Colvert et al, 2002; Misseri et al, 2005; Albouy et al, 2007). All are usually secured to the anterior rectus fascia on either side. Autologous fascial tissue has been used combining the benefits of a compressive wrap and suspension of the proximal urethra and bladder neck. Several variations of fascial placement and configuration have been described (Woodside and Borden, 1982; McGuire et al, 1986; Elder, 1990; Perez et al, 1996a; Bugg and Joseph, 2003; Dik et al, 2003). When fascial slings and wraps are used for neurogenic sphincter incontinence, there is not as much concern for creating a wrap or sling that is too tight because most patients are preferentially managed with CIC. Placement of a bladder neck sling using laparoscopic and robotic assistance is currently being explored by minimally invasive surgeons (Storm et al, 2008; Mattioli et al, 2010; Bagrodia and Gargollo, 2011). Magnification and access to the bladder neck in the deep pelvis appear to aid in the dissection and placement.

Results

Fascial slings have been used more extensively and with better results in girls with neurogenic sphincter incompetence, although recently some success has been reported in boys. Overall, long-term success with fascial slings in the neurogenic population has varied greatly from 40% to 100% (Kryger et al, 2000). A variation thought to contribute to a higher success includes a circumferential fascia wrap around the bladder neck. A circumferential wrap may equalize the compressive pressure over a greater surface area of bladder neck and posterior urethra (Walker et al, 1995; Strang et al, 2006). With the wrap, simultaneous suspension has also been used (Bugg and Joseph, 2003). Success rates have varied so

much that it is difficult to determine whether any modification of the sling accounts for an increase in continence. Most patients who have undergone a fascial sling or wrap have also had simultaneous bladder augmentation. **Success of the sling, as with most repairs, appears to be improved with augmentation cystoplasty in this patient population by almost all reports (Castellan et al, 2005).** Perez and associates (1996a) reviewed the outcome of sling cystourethropexy in 39 children, 15 of whom were boys. One of four various techniques was performed. When evaluating postoperative continence based on age, sex, underlying diagnosis, preoperative urodynamics, surgical technique, and enterocystoplasty, only concomitant enterocystoplasty was predictive of a successful outcome. This was not the experience of Snodgrass, who reported successful outcome of bladder neck sling without the need for enterocystoplasty. Snodgrass and colleagues (2010) reported manageable bladder hostility in their determination, but no need for augmentation, in 26 patients who underwent a sling only. They achieved continence in 46% of 35 patients undergoing a sling alone and 82% of 17 patients undergoing a sling combined with a Leadbetter-Mitchell bladder neck repair (Snodgrass and Barber, 2010).

Unlike with the Silastic sheath, erosion rarely occurs with fascial slings. Gormley and colleagues (1994) reported a revision rate with fascial slings of 15%. Placement of a fascial sling does not eliminate the possibility of later placement of an AUS (Decter, 1993; Barthold et al, 1999). It is not unreasonable to consider placing a fascial sling in a child with a marginally competent bladder neck and deficient external sphincter if the child is undergoing augmentation cystoplasty and already requires intermittent catheterization.

Bladder Neck Bulking Agents

Vorstman and colleagues (1985) reported one of the initial descriptions of injection therapy with a bulking agent into the bladder neck of incontinent children. The initial enthusiasm for use of polytetrafluoroethylene was quickly tempered because of concern over migration of particles to regional and distant sites including pelvic nodes, lungs, brain, kidney, and spleen found in animal models (Malizia et al, 1984). The technique remains of interest, and several alternatives to polytetrafluoroethylene have been assessed, including glutaraldehyde cross-linked collagen, dextranomer/hyaluronic acid copolymer, and polydimethylsiloxane (Leonard et al, 1990a; Guys et al, 2006; Knudson et al, 2006; Lottmann et al, 2006; Dean et al, 2007; Alova et al, 2012a). Bovine collagen should not be used in latex-sensitive children with spina bifida because the product is not latex free (Kryger et al, 2000). In an attempt to achieve an ideal substance for injection, investigation is ongoing using autologous cartilage cells harvested from a separate site then grown in an alginate matrix for endoscopic implantation (Bent et al, 2000). Preliminary results show a positive effect in women with stress incontinence. Whether this or other materials will be appropriate alternatives for neurogenic sphincter incontinence in children is yet to be seen.

To alleviate the risks of injecting a foreign biologic product, alternatives to collagen and bovine have been investigated. Polydimethylsiloxane is one such agent. It is composed of sterile solid textured silicone particles, with an average size of 200 µg, suspended in a biologic hydrogen carrier. The large size of the particles should virtually eliminate lymphatic and distant migration (Beisang and Ersek, 1992; Guys et al, 1999; Halachmi et al, 2004; Guys et al, 2006). Contemporary reports favor the use of dextranomer/hyaluronic acid (Lottmann et al, 2006; Dean et al, 2007; Dyer et al, 2007; Kitchens et al, 2007; Kaye et al, 2010; Alova et al, 2012a).

Technique

Endoscopic exposure is used for localizing the proximal urethra and bladder neck. Injection can be done directly through the working channel of the endoscope, often one with an offset lens system.

Ideal placement of the material is in a subepithelial space mobilizing the epithelium toward the lumen of the bladder neck. When completed in a circumferential fashion, adequate epithelial coaptation may occur, which can raise outlet resistance. Alternatively, periurethral injection in women through a long needle placed from the perineum or via a suprapubic approach has been used. [Dean and colleagues \(2007\)](#) advocate a combined antegrade and retrograde approach. Evidence is lacking regarding whether the exact approach affects success, but accurate placement is important and transurethral injection is usually preferred.

Results

The durability and success of bladder neck and proximal urethral injection remain in doubt for the pediatric population, particularly those with neurogenic dysfunction. True continence, as defined by a 4-hour dry period between voidings or catheterizations, has been reported to be at most 78% and has ranged as low as 5% ([Leonard et al, 1990a](#); [Capozza et al, 1995](#); [Bomalaski et al, 1996](#); [Perez et al, 1996b](#); [Sundaram et al, 1997](#); [Silveri et al, 1998](#); [Guys et al, 2001](#); [Godbole et al, 2003](#); [Halachmi et al, 2004](#); [Dean et al, 2007](#); [Kitchens et al, 2007](#); [De Vocht et al, 2010](#); [Kaye et al, 2010](#); [Alova et al, 2012a](#); [Dajusta et al, 2013](#)). Several factors play a role in the outcome, one of which is a history of any previous operative bladder neck repair. Success is enhanced by elevation of the epithelium of the bladder neck, which may be compromised by scarring from previous operative procedures. **The concept of a minimally invasive operation used to enhance a marginal result gained from a more formal bladder neck repair is enticing; unfortunately, the data are lacking to show that bladder neck injection is of lasting value or that repeat treatments are warranted in that setting** ([De Vocht et al, 2010](#); [Alova et al, 2012a](#); [Dajusta et al, 2013](#)).

[Sundaram and colleagues \(1997\)](#) reported on the efficacy and durability of glutaraldehyde cross-linked bovine collagen in 20 children, 12 of whom had neurogenic sphincter dysfunction. Over half of the children required two or three independent injections. Success was achieved in only 1 patient (5%) who was considered dry; 5 had some improvement, and 10 had either no change or transient improvement for only 2 to 90 days. In the hands of these researchers, collagen therapy only delayed the ultimate need for bladder neck reconstruction. Submucosal bladder neck injection of bovine dermal collagen was used by [Perez and colleagues \(1996b\)](#) in 32 patients. Continence was achieved after a single injection in only 20% of the children with neurogenic dysfunction. The authors concluded that even though their success was limited, the low morbidity and ease of placement justified a trial of submucosal injection in selected children.

[Guys and associates \(2006\)](#) treated 49 children with polydimethylsiloxane, 41 of whom had neurogenic bladder neck and sphincter incontinence. The level of continence deteriorated through 18 months after the procedure, then stabilized. After an average follow-up of 73 months, success had been achieved in 16 (33%), and 7 (14%) were improved. [Godbole and associates \(2003\)](#), [Halachmi and colleagues \(2004\)](#), and [Dyer and coworkers \(2007\)](#) independently came to the conclusion that regardless of the material injected (polytetrafluoroethylene, collagen, polydimethylsiloxane, dextranomer/hyaluronic acid), short-term success is not long lasting. [Alova and colleagues \(2012b\)](#) determined that failure after 1 year using dextranomer and hyaluronic acid was primarily caused by neurogenic bladder dysfunction and deterioration. However, failure after injection therapy does not preclude a successful outcome when it is salvaged by more invasive measures ([Alova et al, 2012b](#)).

The cost of the bulking agents can be excessive, and there does not appear to be any financial benefit over a formal repair ([Kryger et al, 2000](#)). At present, bulking agents play a limited role for increasing outlet resistance and should be reserved for a very select group of patients. **The exact criteria that define that group have not been well established.** Patients with marginal native outflow resistance are probably better candidates than those with minimal preoperative function.

Artificial Urinary Sphincter

The AUS has been recognized as a device that can result in prompt continence in select children while preserving their ability to void spontaneously. The AUS was introduced by [Scott and colleagues \(1974\)](#). The general concept and design of the initial model have been retained; however, improvements and enhancements have evolved that have a positive impact on the long-term success of the AUS. The current AS800 model includes a seamless, pressurized balloon reservoir, nonkink tubing, and changes in the cuff that facilitate its placement and effectiveness with coaptation of the bladder neck and proximal urethra ([Light and Reynolds, 1992](#); [Barrett et al, 1993](#); [Ruiz et al, 2006](#); [Lai et al, 2007](#); [Catti et al, 2008](#)). Alternatives to the AS800 model have also been explored ([Vilar et al, 2004](#); [Farrugia et al, 2012](#)).

Technique

Placement of the cuff should be at the level of the bladder neck in all females and prepubertal boys ([Fig. 145-3](#)). It is also the most desirable and effective location in pubertal and adult males with neurogenic sphincter incompetence. The bulbar urethra can be used as an alternative site in men with mature spongiosum. [Levesque and colleagues \(1996\)](#) have indicated that age is not a factor regarding placement of the cuff around the bladder neck. They found that children do not outgrow the AUS as they progress through puberty and that replacement of the cuff is not routinely necessary. The AUS cuff can be positioned around intestinal segments used in total urinary reconstruction but are more prone to erosion there. Several authors have described the successful placement of the cuff around a bowel segment, particularly when omentum is interposed between the cuff and the segment ([Burbige et al, 1987](#); [Weston et al, 1991](#); [Light et al, 1995](#)).

Placement of an AUS in children is the same as that described for adults. Development of the proper plane for the cuff is virtually identical to that described for a fascial sling. The cuff should be sized snugly, but not tightly, around the bladder neck. Obviously a sterile environment is critical when considering placement of the AUS to avoid infection. For that reason, preoperative antibiotics are a necessity, and confirmation of sterile urine required. With those precautions, there is freedom to open the bladder when dissecting around the bladder neck. This often will facilitate the dissection and ensure proper placement. The AS800 model has a locking mechanism in the pump that permits the AUS to be deactivated and activated without a second operative procedure. Experience has shown that leaving the unit deactivated with the cuff deflated after placement allows formation of a pseudocapsule around the cuff and decreases the risk of erosion ([Furlow, 1981](#); [Hanna, 1981](#); [Sidi et al, 1984](#)). The noncycled AUS occasionally may provide enough resistance for continence, eliminating the disadvantages of activation ([Herndon et al, 2004](#)).

Results

There are substantial short- and long-term data regarding continence after placement of the AUS, with the largest series presented by [Herndon and associates \(2003\)](#). **In investigation of continence, it must be placed in context of the cost experienced by the patient, defined by mechanical malfunctions resulting in secondary operative procedures and more catastrophic complications such as device infection or erosion.** Dramatic improvement regarding the need for secondary procedures has occurred because of the technical refinements in the device. Ten- to 15-year long-term follow-up of the AUS in children has been reported ([Levesque et al, 1996](#); [Kryger et al, 1999](#); [Castera et al, 2001](#); [Kryger et al, 2001](#); [Hafez et al, 2002](#); [Herndon et al, 2003](#); [López Pereira et al, 2006](#); [Ruiz et al, 2006](#)). All groups report an impressive continence rate of 80% and a functioning sphincter in 95% of patients. These reports are consistent with older series in children that reported continence rates of 75% to 90% and a functioning sphincter in 85% to 97% ([Nurse and Mundy, 1988](#); [Gonzalez et al, 1989a](#); [Bosco](#)

Figure 145-3. Artificial urinary sphincter placement in children. A, The cuff is placed around the bladder neck in prepubertal children. Dissection may be facilitated by palpation of a urethral catheter and balloon or by a posterior approach. If dissection is difficult, the bladder can be opened. B, The reservoir is placed beneath the rectus muscle. C, A tunnel is then made into the scrotum or labia for positioning of the pump on the same side as the reservoir. Tubing connections are made ventral to the rectus fascia, and the device is initially left deactivated.

et al, 1991; O'Flynn and Thomas, 1991; Aprikian et al, 1992; Simeoni et al, 1996; Singh and Thomas, 1996; Ruiz et al, 2006; Catti et al, 2008). Herndon and associates (2003) present the most comprehensive long-term data. They achieved overall continence in 86% of 142 patients with an average follow-up of 10 years. Age at implementation does not appear to affect continence (Kryger et al, 2001).

Although the AUS is one of the few surgically created continence mechanisms that does not negatively affect spontaneous voiding, CIC remains an important adjunct in approximately 75% of children with neurogenic sphincter incompetence and can be performed successfully through the cuff (Diokno and Sonda, 1981; Gonzalez et al, 1995; Levesque et al, 1996; Kryger et al, 1999; Castera et al, 2001; Kryger et al, 2001; Hafez et al, 2002; Herndon et al, 2003; Ruiz et al, 2006; Catti et al, 2008). As boys approach puberty, spontaneous voiding may become progressively inadequate. It has been speculated that growth of the prostate causes an increase in native outlet resistance. Kaefer and colleagues (1997a) evaluated increases in cuff size to facilitate spontaneous voiding in boys. In their limited series, they did not find that upsizing restored the ability to void spontaneously. Jumper and colleagues (1990) reported on prostatic development and sexual function in pubertal boys with spinal dysraphism who had been treated with the AUS. They found that the artificial sphincter did not alter sexual development, prostatic growth, or morphology.

Herndon and associates (2003) reported device malfunction with 64% of the pre-AS800 model and 30% with the AS800. Sphincter erosion was similar for the pre-AS800 and AS800, occurring at 19% and 16%, respectively, in their experience, similar to the reports of others (Ruiz et al, 2006; Bauer, 2008). Fastidious attention to detail and sterile technique diminish the risk of infection but do not eliminate it. When infection occurs without erosion, the unit can be removed and later replaced (Nurse and Mundy, 1988). Infections are minimized by sterilizing the urine preoperatively, meticulously cleaning the wound site, using a preoperative bowel preparation, administering perioperative parenteral antibiotics, and performing copious antibiotic wound irrigation. Newer cuff design and a 6-week delay in activation of the device help formation of a thickened pseudocapsule that substantially decreases bladder neck and proximal urethral erosion. Kryger and colleagues (1999) indicated that erosion can be virtually eliminated when the cuff is placed as the primary treatment for bladder neck incompetence.

They and others (Aliabadi and Gonzalez, 1990; Gonzalez et al, 1995; Levesque et al, 1996; Simeoni et al, 1996; Castera et al, 2001; Hafez et al, 2002; Herndon et al, 2003) noted that the risk of erosion is substantially increased after previous failed repairs, with only Ruiz and colleagues (2006) noting results to the contrary. Identifying the correct plane between the bladder neck and vagina in females or rectum in males preserves the vascularity of the bladder neck and proximal urethra and may decrease the rate of erosion (Aliabadi and Gonzalez, 1990). Initial exposure via a posterior bladder approach may be helpful (Hanna, 1981; Lottmann et al, 1999). Shankar and colleagues (2001) suggested that there is an advantage to exposure of the bladder neck with a transperitoneal approach by decreasing the potential of bleeding from the prostatic venous plexus and improving visualization of the rectal wall.

Levesque and associates (1996) evaluated the long-term outcome of the AUS based on date of insertion and location of the placement. Before 1985 the AUS was inserted in 36 children. From 1985 to 1990, an additional 18 children underwent placement. In the original group, 24 of the 36 sphincters were in place and 22 functional. Twelve had required at least one revision. The mean survival of the device was 12.5 years. Success rates at 5 and 10 years were 75% and 72%, respectively. In the group that underwent implantation after 1985, 78% retained a functioning sphincter. The overall continence rate in both groups was 59%; sphincter survival probability at 10 years was approximately 70%. There was no difference found between failure rates in males and those in females, with the exception that female patients who had previously undergone bladder neck surgery were more likely to develop erosion. The ability to void independently without the use of CIC was retained in 36 (67%) children. Those findings are supported by contemporary series (Levesque et al, 1996; Kryger et al, 1999; Castera et al, 2001; Kryger et al, 2001; Hafez et al, 2002; Herndon et al, 2003; Ruiz et al, 2006; Catti et al, 2008; Bar-Yosef et al, 2011). A meta-analysis of 585 children who had undergone AUS placement was reviewed by Bauer (2008). He reported that 80% of patients with a retained sphincter were continent, with approximately 32% spontaneously voiding. Secondary surgery was required in 28%; 19% had erosion involving the bladder neck, 50% of whom had undergone prior bladder neck surgery. It appeared that use of a low-pressure balloon reservoir (61% to 70% cm H₂O) had been advantageous. Placing only the cuff during bladder augmentation

may provide effective continence with decreased complications as reported by [Viers and colleagues \(2014\)](#).

Upper urinary tract changes including hydronephrosis have been reported to occur in up to 15% of children after placement of the AUS ([Light and Pietro, 1986](#); [Churchill et al, 1987](#); [Gonzalez et al, 1995](#); [Levesque et al, 1996](#); [Kryger et al, 1999](#)). In extreme cases, renal insufficiency has resulted. It is now recognized that occlusion of the bladder neck in children with neurogenic sphincter incompetence can result in the unmasking or development of detrusor hostility manifesting with a decrease in bladder compliance or increase in detrusor overactivity ([Bauer et al, 1986](#); [Bauer, 2008](#)). Careful preoperative urodynamic assessment helps to identify only some of the children who are at risk ([Kronner et al, 1998b](#); [Dave et al, 2008](#)). When hostile bladder characteristics are found preoperatively, anticholinergic medications can be beneficial for hyperreflexic contractions, but augmentation cystoplasty is usually required for diminished compliance. [Churchill and associates \(1987\)](#) showed that favorable parameters can be maintained after placement of the AUS; however, close observation is still recommended in any child undergoing bladder neck reconstruction to identify any early deterioration in bladder dynamics before upper tract changes.

Some children undergoing sphincter placement need bladder augmentation as well, and the timing of the two procedures may be questioned owing to the concern for AUS infection. [Light and colleagues \(1995\)](#) reported a 50% infection rate with simultaneous augmentation compared with 9.5% when the procedures were staged. To the contrary, a contemporary review by [Miller and coworkers \(1998\)](#) found infection necessitating removal of the device occurred in only 2 of 29 such patients (7%). This low rate is similar to that noted by others ([Gonzalez et al, 1989b](#); [Strawbridge et al, 1989](#)). Several reports have evaluated various factors and found that the intestinal segment selected for augmentation appeared to be the only parameter affecting results; gastric augmentation was the least offensive regarding infection ([Ganesan et al, 1993](#); [Miller et al, 1998](#); [Holmes et al, 2001](#)). [Gonzalez and colleagues \(2002\)](#) reported an alternative technique using a seromuscular colocolostomy and simultaneous placement of the AUS. They achieved continence in 89% without the need for additional procedures and with no deterioration of the upper urinary tract. Although infection of the AUS is a concern, placement can be successfully undertaken when bowel is simultaneously used for total continent reconstruction of the bladder and bowel ([Bar-Yosef et al, 2011](#)).

The AS800 is the subject of most reviews when discussing the AUS, but alternative devices have been reported. [Lima and associates \(1996\)](#) and [de O Vilar and colleagues \(2004\)](#) reported on the combined use of enterocystoplasty and a "new type" of AUS. The new device is a one-piece adjustable cuff connected to an inflatable port. The cuff provides static, fixed resistance that enhances continence and allows for intermittent catheterization. The injection port is placed subcutaneously and made available for percutaneous access to adjust the fluid volume and pressure of the cuff needed to maintain continence. It is particularly convenient for individuals with limited ability to actively pump the AS800. [Farrugia's group \(2012\)](#) in particular has reported good early results with the alternative device.

The ultimate benefits of the AUS lie in its ability to achieve a high rate of continence while maintaining the potential for spontaneous voiding. For practical purposes, when intermittent catheterization is required along with augmentation cystoplasty, use of native tissue for continence eliminates the long-term concern for infection or erosion and the risk of mechanical failure.

Urethral Lengthening

[Young's original description of bladder neck reconstruction \(1919\)](#) consisted of two components: excision of a segment of anterior urethral bladder neck tissue and narrowing of the adjacent remaining posterior portion. This, however, ultimately led to failure because the tubularized segment remained unsupported within the

bladder. Refinements by [Dees \(1949\)](#) and [Leadbetter \(1964\)](#) maximized good muscle tone at the bladder neck and extension of the urethral tube through the trigone.

[Tanagho \(1981\)](#) described a cephalad-based anterior detrusor wall tube. Closure of the tubularized bladder neck created circularly oriented muscle fibers, which Tanagho described as a sphincter mechanism. He, however, cautioned against the use of this technique in the neurogenic population. Because of potential breakdown of that tubularized bladder neck and poor results, other techniques have been developed based on the concept of a flap valve mechanism for urinary retention. [Kropp and Angwafo \(1986\)](#) described urethral lengthening and creation of a flap valve for neurogenic bladder neck and sphincter dysfunction. The technique is based on an anterior detrusor wall tube that is kept in continuity with the urethra, tubularized, and implanted into a submucosal tunnel within the trigone. Conceptually this is effective; however, difficulty with catheterization is a common problem and significant concern.

Technique

A Foley catheter is placed intravesically and the bladder filled to capacity. The bladder is exposed through either a midline or low transverse abdominal incision. The bladder neck is then identified with application of gentle catheter traction. A 6- × 2-cm rectangular flap based on the bladder neck and urethra is then isolated. Stay sutures are placed, and the flap is mobilized in continuity with the proximal urethra. The detrusor musculature at the bladder neck is divided, separating the bladder and urethra, or the muscle may be left intact at the 5 and 7 o'clock positions. In girls the anterior vaginal wall is exposed; in boys, the seminal vesicles. The rectangular strip based on the urethra is tubularized posteriorly around the urethral catheter with a continuous absorbable suture. The distal portion of the tubularized strip should be approximated in an interrupted fashion to facilitate excision of excessive tissue without jeopardizing the suture line. A capacious submucosal tunnel through the trigone is then created posteriorly for the neourethra ([Fig. 145-4](#)). A wide tunnel is required in order to prevent kinking at the level of the bladder neck, which would impede catheterization. It is important to eliminate dead space at the entrance of the urethra into the bladder; this can be accomplished by placing lateral anchoring sutures in the region of the bladder neck. The detrusor tube must be pulled straight through the tunnel without curve or deviation to facilitate catheterization. [Waters and colleagues \(1997\)](#) and [Kropp \(1999\)](#) have not found it necessary to reimplant all ureters in a cephalic location; they now typically reimplant only refluxing ureters ([Kropp, 1999](#)). When closing the bladder, the lateral wings in the region of the bladder neck are approximated and incorporate adventitia of the tubularized urethra. This enhances a watertight closure and is continued for 2 to 3 cm anteriorly, often up to the area of augmentation. The tubularized neourethra should be long enough to reach the true lumen of the bladder, where it is exposed to pressure as an effective flap valve.

Because of the difficulties with catheterization, modifications of the Kropp bladder neck procedure have been described. [Belman and Kaplan \(1989\)](#) suggested a simplified approach. They harvested a rectangular strip from the anterior bladder wall similar to that described by Kropp. The lateral and posterior musculature at the bladder wall, however, is not incised, and the proximal urethra and bladder are not separated. The flap is tubularized over an 8-Fr catheter. The epithelium on the floor of the bladder is incised contrary to the tunnel made by Kropp. The tube is placed within the trough with the proximal meatus secured on the floor of the bladder. The epithelial edges of the trough are then secured to the lateral aspect of the tube. As with the initial description, the suture line for tubularization of the urethra lies posteriorly against trigonal muscle. Closure of the bladder begins with reapproximation of the lateral walls of the bladder to the tube until the bladder edges meet. The remaining portion of the bladder is covered by an augmentation. Regardless of any modification to the Kropp bladder neck procedure, catheterization potentially remains problematic, and

Figure 145-4. Kropp anterior detrusor tube. **A**, An anterior flap of bladder (2 cm wide \times 5 to 6 cm long) is developed in continuity with the urethra. **B**, The anterior flap is tubularized over a catheter. A tunnel beneath the mucosa of the trigone is made between the ureteral orifices for the length of the tube. **C**, The tubularized flap is brought through the tunnel. **D**, The detrusor tube is secured to the floor of the trigone with interrupted absorbable suture in a straight course.

therefore the patient should be prepared for a catheterizable abdominal-vesicle channel.

An innovative trial by [Chrzan and colleagues \(2013\)](#) was undertaken in 18 patients, using laparoscopic techniques that allowed for "vesicoscopic" exposure of the bladder neck. Chrzan and coworkers were able to lengthen the urethra by creating a U incision around the bladder neck and onto the epithelial surface of the bladder dome. This prevented interference of the ureteral orifices and could be undertaken in patients in whom other bladder neck procedures had failed. Unfortunately, a long-term benefit has not been achieved.

Results

[Snodgrass \(1997\)](#) examined the results in 23 children, 22 of whom had neurogenic sphincter incompetence, and noted continence in over 90% of the children. The most common complication was difficult catheterization, particularly in boys. Less than half of the boys in Snodgrass's series catheterized through the native urethra; the majority did so via an abdominal wall stoma. Postoperative vesicoureteral reflux was identified in 9 of 18 children, and Snodgrass speculated this was because of lateral retraction of the ureters. Their recommendation was made to leave the posterior bladder wall

open and flat when receiving the augmentation in order to prevent this distortion. Kropp (1999) has not had as much difficulty with catheterizations in his patients and likewise has achieved a high rate of continence without a high incidence of new reflux.

Some patients with an effective flap valve mechanism created by urethral lengthening will virtually never leak per urethra. This potentially puts them at risk for upper tract deterioration or bladder rupture, particularly if they do not or cannot catheterize reliably. Snodgrass (1997) thought that his modification was beneficial in that it resulted in a shorter intravesical tunnel for the neourethra, allowing for leakage per urethra with overfilling.

Pippi Salle Procedure

In an attempt to maximize the benefits of the Kropp technique and decrease problems with catheterization, Salle and associates (1994) reported an anterior bladder onlay flap. With this technique, the posterior wall of the neourethra is intact, theoretically providing less potential hang-up during catheterization. Since the first report, modifications have been made to improve flap viability, minimize fistula formation, and extend the indications for the procedure beyond that of the neurogenic bladder (Salle et al, 1997).

Technique

An anterior, full-thickness bladder wall flap 5×1 cm is mobilized to the bladder neck with 0.1 cm of its epithelial edges excised to avoid overlapping suture lines. Two parallel incisions down to the level of the muscle are made in the mucosa of the trigone from the native bladder neck. The anterior flap is secured to the midline strip of trigone mucosa to create a tube or lengthened urethra using absorbable suture. The muscle on either side of the posterior epithelial strip may be incised superficially to provide an edge to which the muscle of the anterior flap may be approximated with a second layer of suture in an effort to avoid fistula (Fig. 145-5). The more lateral mucosa of the trigone is mobilized and closed over the midline urethra. Distally, the muscle of the bladder neck is wrapped tightly around the urethra with closure. Proximally, the lengthened urethra should extend well into the lumen of the bladder.

Results

Initial complications of this procedure included persistent incontinence, urethrovesical fistula, and partial necrosis of the intravesical neourethra. Widening the base of the urethra at the level of the bladder neck may minimize these problems. Children who have previously undergone bladder surgery can have a secondary Salle repair if the anterior bladder flap is lateralized slightly to avoid any old midline suture line.

Salle and coworkers (1997) found that continence was achieved in 12 of 17 patients (71%) for more than 4 hours. Catheterization difficulties occurred in only 3 of 17 children, 1 of whom subsequently underwent an appendicovesicostomy. Fistula formation at the base of the flap between the proximal, intravesical urethra and bladder occurred in 2 children and resulted in recurrent incontinence. This problem appears to be diminished by creating a wider base to the flap and generously trimming the epithelial edges there. Jawaheer and Rangecroft (1999) reported a diurnal continence rate of 61% for 3 or more hours with the Salle procedure. However, only 44% of their patients were dry through the night. Less trouble with catheterization has occurred relative to the Kropp technique and rarely remains a problem. Continence rates have not been quite as high in most series (Rink et al, 1994; Mouriquand et al, 1995; Cole et al, 2003).

Canales and associates (2006) used a miniature intravesical lengthening of shorter length (3 cm) and radius (8 Fr) with the intent of enhancing resistance, minimizing the use of bladder, and avoiding need for ureteral reimplantation. After 2.5 years of follow-up, 8 of 9 children were continent and had an average leak point pressure of 71 cm H₂O.

Bladder Neck Division

The ultimate procedure to increase bladder outlet resistance is to divide the bladder neck so that it is no longer in continuity with the urethra. It must be accompanied by creation of a continent abdominal wall stoma and should be performed only in patients who will reliably catheterize. If effective, it prevents any leakage or pop-off per urethra and increases the risk for upper tract deterioration or bladder rupture if emptying is not performed. Division is seldom performed as a primary procedure but may be considered if the previously mentioned repairs fail (Khoury et al, 1999; Bergman et al, 2006; Landau et al, 2009; De Troyer et al, 2011; Baradaran et al, 2012; Kavanagh et al, 2012).

Closing the bladder neck moves the reconstructive effort into the realm of continent urinary diversion. The bladder neck is abandoned from a physiologic standpoint, although the bladder may be used as part of the reservoir. Effective division of the bladder neck is not a simple procedure. The bladder must be aggressively mobilized away from the urethra. The bladder should be closed distally in several layers after the posterior lip of bladder neck and trigone are rolled anteriorly and widely separated from the distal urethra. Omentum has usually been interposed, as has rectus abdominus muscle (Smith et al, 2010). Without these steps, fistulization and leakage per urethra can occur (Khoury et al, 1999; Nguyen and Baskin, 2003). With aggressive mobilization, the fistula rate can be low (Thomasch et al, 2009). Although eliminating secondary access to the bladder creates a concern, long-term follow-up indicates that a successful outcome is achieved in almost all patients (Landau et al, 2009; De Troyer et al, 2011; Kavanagh et al, 2012).

KEY POINTS: BLADDER NECK RECONSTRUCTION

- Any repair other than placement of an AUS, particularly if combined with cystoplasty, is likely to make spontaneous voiding inadequate.
- Young-Dees-Leadbetter repair in the spina bifida population has variable success related to the underlying neurogenic dysfunction.
- Fascial slings have been used more extensively and with better results in girls than boys with neurogenic dysfunction, although those results vary widely.
- Experience does not yet suggest that injection of bladder neck bulking agents has a lasting effect on severe neurogenic sphincter incompetence.
- A functioning, well-positioned artificial sphincter provides good resistance and is best reserved for patients who can empty adequately with spontaneous voiding.
- Urethral lengthening procedures use a flap valve mechanism for continence that disrupts any chance of voiding and may make catheterization per urethra difficult.
- The success of most bladder neck repairs in the neurogenic population improves if combined with augmentation cystoplasty.
- Bladder neck repair may unmask or result in new bladder hostility; careful follow-up is mandatory.

AUGMENTATION CYSTOPLASTY

The initial approach to the patient for augmentation cystoplasty is similar regardless of the bowel segment to be used. Cystoscopy may be performed preoperatively to identify any unsuspected anatomic abnormalities that may affect the surgery or postoperative care. If other bladder procedures such as ureteral reimplantation are to be performed, the bladder is left full after cystoscopy. If not, the bladder is emptied to allow easy access to the peritoneal cavity.

As a general rule, a midline incision is preferred for intestinal cystoplasty, although these procedures can be performed through a lower transverse incision if there has been no previous

Figure 145-5. Pippi-Salle anterior detrusor tube only. A, An anterior detrusor tube (1 cm × 4 to 5 cm) is mobilized to the level of the bladder neck. B, A central strip on the floor of the bladder is developed by incision of the epithelium on either side. C, The anterior detrusor flap is secured to the strip in a two-layer fashion, approximating the epithelium with the first layer and muscle with the second. D, The lateral mucosa of the trigone is mobilized and secured over the lengthened urethra. Distally, the bladder is closed to itself and should incorporate a portion of the anterior detrusor flap to ensure a watertight seal. E, After distal closure the remaining portion of the bladder is left open if augmentation cystoplasty is necessary.

Figure 145-6. Cystogram after augmentation demonstrates a narrow anastomosis of the bowel segment to bladder. The segment behaves like a diverticulum.

abdominal surgery. Laparoscopic assistance with mobilization of the intestine may allow augmentation through a smaller, lower incision (Hedican et al, 1999). Associated bladder procedures should be performed before opening the peritoneal cavity to minimize third space fluid loss. For gastrocystoplasty, the incision extends from the pubis to the xiphoid to allow more cephalad exposure. Augmentation cystoplasty may be performed completely by laparoscopy with or without use of a robotic system (Lorenzo et al, 2007; Wang et al, 2007; Passerotti et al, 2008). For such cases, a 12-mm camera port is placed periumbilically or supraumbilically, and up to four 5- to 8-mm working ports are used; one working port should be larger if an endostapler is to be used. Assistant ports are optional, and the use of the fourth robotic arm may aid with retraction or passage of sutures (Gundeti et al, 2008).

Management of the Native Bladder

In the past, it had been recommended that the majority of the “diseased” bladder be excised in preparation for augmentation. This meant removal of the supratrigonal bladder, leaving only a small cuff for anastomosis to the intestinal segment. Despite the cuff, a relatively small area was left for anastomosis to the bowel segment; most of the bowel was approximated to itself. Most surgeons now preserve the native bladder as long as it is widely opened to prevent a narrow-mouthed anastomosis, which can result in the augmentation segment behaving as a diverticulum (Fig. 145-6). A sagittal incision to bivalve the bladder is generally useful (Fig. 145-7). The incision is carried from a point several centimeters cephalad to the bladder neck anteriorly to a position just above the trigone posteriorly. Such an incision allows a technically easier anastomosis to the bowel segment and leaves the native bladder to add to the overall capacity. A greater circumference for the anastomosis can be provided if need be, by opening the bladder in a stellate fashion with a second transverse incision into the two bladder halves. There have been reports of penile or perineal pain

Figure 145-7. The native bladder can be managed by supratrigonal excision of the diseased bladder. More typically, the bladder is opened widely in a sagittal plane (left).

in sensate boys after augmentation with preservation of the native bladder (Phelps and Malone, 2004). Although four such patients required secondary removal of bladder, similar problems have not been frequent enough to warrant routine excision at the time of augmentation.

Management of Intestinal Segments

Hinman (1988) and Koff (1988) demonstrated the advantages of opening a bowel segment on its antimesenteric border with subsequent detubularization and reconfiguration of that intestinal segment. Reconfiguration into a spheric shape provides multiple advantages, including maximization of the volume achieved for any given surface area, blunting of bowel contractions, and improvement of overall capacity and compliance. All intact, tubular intestinal segments have been noted to generate pressures of 60 to 100 cm H₂O with contractions (Kock, 1969; Light and Engelmann, 1985; Fowler, 1988; Camey et al, 1991). Detubularization lowered the maximal contractile pressure from 63 to 42 cm H₂O in the right colon and 81 to 28 cm H₂O in ileum (Goldwasser et al, 1987). Furthermore, a shorter intestinal segment can be used to achieve the same capacity than when left in tubular form. Detubularization and reconfiguration should always be performed during augmentation cystoplasty.

Mathematical models based on the length and width of the bowel segment used may predict the volume needed but are cumbersome (Rink and Mitchell, 1990). Depending on the volume needed, 20 to 40 cm of ileum or approximately 20 cm of colon are typically used for cystoplasty. This somewhat depends on the volume of the native bladder being augmented. If the cystoplasty is being done on a bladder of moderate volume that generates high pressure by uninhibited contractions, less bowel is necessary than for one that is tiny in capacity. Unless otherwise contraindicated, the surgeon should err by making the bladder too large rather than too small. Appreciation of the patient's urinary volumes also should influence the size of the bladder required. Patients with upper tract damage may make huge volumes of urine and require a larger capacity.

Ileocystoplasty

Goodwin and associates (1959) were among the first to demonstrate the numerous ways to anastomose a patch of ileum to the native bladder after the ileum was detubularized and reconfigured to achieve the most spheric shape possible.

Figure 145-8. A, Ileocystoplasty. A 20- to 40-cm segment of ileum at least 15 cm from the ileocecal valve is removed and opened on its antimesenteric border. Ileoileostomy reconstitutes the bowel. B, The opened ileal segment should be reconfigured. This can be done in a U, S, or W configuration. It can be further folded as a cup patch. C, The reconfigured ileal segment is anastomosed widely to the native bladder.

Technique

A segment of ileum at least 15 to 20 cm proximal to the ileocecal valve should be selected. The distal portion of terminal ileum is unique from a physiologic standpoint and should be avoided. The isolated segment should be 20 to 40 cm in length depending on patient size, native bladder capacity, and the desired final capacity. With short ureters, an extra tail of isoperistaltic ileum can be useful to reach the foreshortened ureters. This would require creation of an ileal nipple valve to prevent reflux as in the Kock or hemi-Kock pouch; this type of construction may require up to 60 cm of small intestine. **The segment to be used should have an adequate mesentery to reach the native bladder without tension.** After selection of the appropriate segment, the mesentery is cleared from the bowel at either end for a short distance to create a window. The bowel is divided at those ends, and a hand-sewn ileoileostomy or stapled anastomosis is performed. The mesenteric window at the bowel anastomosis is closed to prevent an internal hernia. The harvested

ileal segment is irrigated clear with 0.25% neomycin solution and opened on its antimesenteric border (Fig. 145-8A). The ileum is folded in a U shape most commonly, although longer segments can be folded further into an S or W configuration. The ileum is anastomosed to itself with running absorbable sutures (Fig. 145-8B). The suture line should approximate the full thickness of ileum to ileum while inverting the mucosa. The anastomosis of the ileum to native bladder is easily done when started posteriorly. The anastomosis may be done in a one- or two-layer fashion, always using absorbable suture and inverting the mucosa to the lumen (Fig. 145-8C). Permanent sutures should never be used for any cystoplasty because they serve as a nidus for stone formation. A suprapubic tube is brought through the native bladder when possible and secured. The anterior aspect of the anastomosis is then completed. A drain is placed near the bladder and brought out of the pelvis through a separate stab incision. It should be removed promptly if not draining urine, particularly in neurogenic patients with a ventriculoperitoneal shunt.

Cecocystoplasty and Ileocecocolostomy

Couvelaire (1950) described the use of the cecum for augmentation cystoplasty, and numerous reports followed. Presently, cecocystoplasty is an uncommon operative procedure and will not be discussed because it has largely been replaced by various forms of ileocecocolostomy. With this technique, the cecum is opened, reconfigured, and used to augment the bladder alone, leaving a segment of ileum to reach the ureters or create a continent abdominal wall stoma. Conversely, the ileal segment can be opened and used as a patch on the cecal segment before augmentation cystoplasty.

Technique

Many modifications of the technique exist, but all start with mobilization of the cecum and right colon by incising the peritoneum along the white line of Toldt up to the hepatic flexure. Fifteen to 30 cm of the terminal ileum are used. The length of the ileal segment depends on the technique used. As with all intestinal cystoplasties, before division of the bowel segment, it should be noted that it will reach the bladder without tension (**Fig. 145-9A**).

The isolated ileocecal segment is irrigated clear with neomycin solution and opened on its antimesenteric border through the ileocecal valve for its entire length. In the typical ileocecal augmentation, the ileal and cecal segments are of equivalent length such that the borders of the open segment can be anastomosed and then folded on themselves to form a cup cystoplasty (**Fig. 145-9B**). The anastomosis of the reconfigured segments is done in either a one- or two-layer closure with absorbable suture. The opening should be left large enough to provide a wide anastomosis to the bivalved bladder. If more volume is necessary, the ileal segment can be significantly longer, allowing it to be folded before anastomosis to the cecum. The Mainz ileocecocolostomy uses an ileal segment twice the length of the cecal segment. The compound ileocecal patch is then anastomosed to the bladder (**Fig. 145-10**). The mesenteric window is closed, and a suprapubic tube is placed through the native bladder and secured through the abdominal wall.

Appendix

One potential advantage of ileocecocolostomy is the presence of the appendix. Particularly in children, the appendix is useful in

creation of a reliable continent abdominal wall stoma. The appendix may be removed with a small cuff of cecal wall and tunneled into the native bladder or a tenia of the cecal segment to provide a continence mechanism. Likewise, it may be left in situ and the base safely tunneled beneath a tenia. If the appendix is not to be used, an appendectomy is performed with standard ileocecocolostomy.

Ileocecal Valve

The ileocecal segment has been used extensively in the adult population undergoing reconstruction and bladder replacement. It has been used less frequently in children because the majority of patients undergoing augmentation cystoplasty do so for neurogenic dysfunction affecting both bladder and bowel. Removal of the ileocecal valve in such children can result in intractable diarrhea (**Gonzalez and Cabral, 1987; King, 1987**). Use of the ileocecal valve in such patients should be avoided unless other advantages of the segment outweigh the risk of diarrhea and fecal incontinence.

There are potential advantages to the use of the ileocecal segment. Antireflux tunnels can easily be performed into the tenia of the cecum when necessary. Again for the short ureter, a tail of ileum can be left intact to bridge the gap and the imbricated ileocecal valve used for antireflux. The same imbrication technique can be used to create a continent abdominal wall stoma similar to that used in the Indiana Pouch (**Cain and Husmann, 1994; Cain et al, 1999**).

Sigmoid Cystoplasty

Use of the sigmoid colon for augmentation cystoplasty was first reported by Lemoine in 1912 (**Charghi et al, 1967**), and it continues to be used commonly. Because of the strong unit contractions of the sigmoid, it is imperative to detubularize and reconfigure the segment to provide maximal compliance and disruption of contractions.

Technique

Fifteen to 20 cm of sigmoid colon are identified and mobilized. The mesentery is transilluminated to identify the vascular arcade to the segment. After identification of this blood supply, the surgeon must ensure that the segment can reach the bladder without tension. The bowel segment is divided between clamps, and a colocolostomy performed (**Fig. 145-11A**). The remainder of the abdominal cavity

Figure 145-9. Ileocecocolostomy. A, An ileocecal segment is selected. The length of segment chosen depends on the technique used. After removal, it is opened on the antimesenteric border (dashed lines). B, The opened ileal and cecal segments are anastomosed to form a cup in the standard ileocecal cystoplasty.

Figure 145-10. The Mainz ileocecostoplasty. A and B, The ileal segment is twice the length of the cecal segment. C and D, It is opened on the antimesenteric border. E and F, The ureters can be reimplanted into the opened cecal segment if necessary. G and H, The ileocecal segment is anastomosed to the native bladder. (From Thuroff JW, Alken P, Hohenfellner R. The Mainz pouch (mixed augmentation with ileum and cecum) for bladder augmentation and continent diversion. In: King LR, Stone AR, Webster GD, editors. *Bladder reconstruction and continent urinary diversion*. Chicago: Year Book; 1987. p. 252.)

should be carefully packed to prevent contamination from the open sigmoid segment. Detubularization and reconfiguration is done in a fashion determined by the surgeon's preference. The sigmoid patch is anastomosed to the bivalved bladder in a manner similar to that previously described for ileocystoplasty. Again, a large suprapubic tube is brought out through the native bladder and secured to the bladder and skin exit sites.

Reconfiguration of Sigmoid. In general, sigmoid colon segments are reconfigured in one of two ways. Mitchell (1986) suggested

closing the two ends and then opening the segment longitudinally opposite its blood supply. The segment easily fits on the bivalved bladder in either the sagittal or coronal plane (Fig. 145-11B). More radical reconfiguration, and perhaps breakup of unit contractions, may be achieved by folding the sigmoid segment in a U shape similar to that described for ileocystoplasty (Sidi et al, 1987a) (Fig. 145-11C). A slightly longer segment of sigmoid may be necessary for effective reconfiguration in this manner.

Gastrocystoplasty

Two basic techniques exist for use of stomach in bladder augmentation.

Technique Using Antrum

Leong and Ong (1972) described the use of the entire gastric antrum with a small rim of body for bladder replacement. With their technique, the left gastroepiploic artery is always used as a vascular pedicle. If the right gastroepiploic artery is dominant and the left vessel ends high of the greater curvature, a strip of body along the greater curvature from the left gastroepiploic artery to the antrum is maintained and provides adequate blood supply (Leong, 1988). Continuity of the upper gastrointestinal tract is restored with a Billroth I gastroduodenostomy.

Technique Using Body

A gastric wedge based on the midportion of the greater curvature may be used (Adams et al, 1988) (Fig. 145-12A). The gastric segment used in this technique is made up mainly of body and consequently has a higher concentration of acid-producing cells. The right or left gastroepiploic artery may be used as a vascular pedicle to this segment. The right artery is commonly dominant and thus more frequently used. The wedge-shaped segment of stomach includes both the anterior and posterior wall. The segment used may be 10 to 20 cm along the greater curvature depending on patient age and size as well as the needed volume (Fig. 145-12B). The incision into the stomach is stopped just short of the lesser curvature to avoid injury to branches of the vagus nerve controlling the gastric outlet. Branches of the left gastric artery just cephalad to the apex of this incision are suture ligated in situ before incision to avoid significant bleeding. Parallel atraumatic bowel clamps are placed on either side of the gastric incisions to avoid excessive bleeding or spillage of gastric contents. The native stomach is closed in two layers using permanent sutures on the outer seromuscular layer.

Branches of the gastroepiploic artery to the antrum on the right or to the high corpus on the left are divided to provide mobilization of the gastroepiploic pedicle. In order that the eventual pedicle is long enough to reach the bladder, the appropriate segment may be higher on the greater curvature if the right vessel is used as a pedicle or lower if based on the left. The vascular pedicle should not be free floating through the abdomen. The segment and pedicle may be passed through windows in the transverse mesocolon and mesentery of the distal ileum and carefully secured to the posterior peritoneum. Despite consideration for an adequate pedicle length, on occasion the gastric segment initially may not reach the bladder without tension. Either gastroepiploic artery may be mobilized closer to its origin for further length. The first few branches from the gastroepiploic artery to the isolated gastric segment may also be divided. Because of the rich submucosal arterial plexus in the stomach, devascularization of the isolated segment does not result. Rarely, it may be necessary to approximate some of the isolated gastric segment to itself in one corner. The gastric segment should be approximated to the native bladder using one or two layers of absorbable sutures, taking care to invert the mucosa (Fig. 145-12C).

Raz and colleagues (1993) and Lockhart and associates (1993) have described the use of a much longer, narrower segment of stomach based along the greater curvature. Use of this segment, which includes both body and antrum, somewhat narrows the

Figure 145-11. Sigmoid cystoplasty. A, A sigmoid segment of adequate length is removed from the gastrointestinal tract, and a colocolostomy is performed. B, In the Mitchell technique the two opened ends are closed. The antimesenteric border is incised, and the segment is anastomosed to the bivalved bladder. It may be rotated 180 degrees to allow an easy fit. C, The opened sigmoid segment can be reconfigured into a U or S configuration, which may lower pressure.

lumen of the stomach along its entire length except at the fundus and pylorus. Raz and colleagues have isolated this segment using a GI stapler so that the native stomach is never open. Postoperative bladder and gastric drainage is no different than that described for intestinal cystoplasty. H₂ blockers are given in the early postoperative period to promote healing (Rink et al, 2000).

Postoperative Management

Early Management

Care of patients after cystoplasty is similar regardless of the segment used in the procedure. Typically, all patients have been maintained on nasogastric decompression until bowel function recovers, although two studies (Gundeti et al, 2006; Erickson et al, 2007) have suggested that nasogastric suction may not be necessary after ileocystoplasty. Attention to fluid and electrolyte management is important because third space losses may be significant after extensive reconstructive surgery. Continuous drainage of the bladder is achieved by suprapubic cystostomy. Mucus production from small or large bowel may be excessive and

can potentially occlude the drainage catheter. **The suprapubic tube should be irrigated at least three times daily and whenever drainage is slowed by mucus.** Extravesical drains may be removed after several days, if drainage of urine is not apparent. The drains are usually removed more promptly in patients with a ventriculoperitoneal shunt to minimize risk of infection. Some surgeons prefer to perform a cystogram before patient discharge; others wait approximately 3 weeks for the study before clamping the suprapubic tube. All patients should begin CIC every 2 to 3 hours during the day and one or two times at night initially. The suprapubic tube is removed after regular catheterization is successfully underway. The duration between catheterizations is gradually increased over several weeks but should not exceed 4 to 5 hours during the day. Patients without neurologic impairment may eventually attempt to void spontaneously. All should check postvoid residual volumes and continue catheterizations if the residuals are significant.

Late Management

Routine radiographic surveillance of the upper urinary tract is indicated at 6 weeks, 6 months, and 1 year after augmentation

Figure 145-12. Gastrocystoplasty with use of the body. A, Gastric segment of body is mobilized on the right gastroepiploic artery. The left vessel may also be used; neither vessel as a pedicle should be free floating through the peritoneum. B, A longer gastric segment along the greater curvature with wider apex provides more surface area for augmentation. C, The gastric segment is anastomosed to the bivalved bladder with the mucosa inverted. (© Indiana University Medical Illustration Department.)

cystoplasty. Most such surveillance may be done with ultrasonography. Serum electrolytes, BUN, and creatinine levels along with urine cultures are performed several times in the first year after surgery. All positive urine cultures need not be treated in patients on CIC. Certainly symptomatic cystitis or infections involving urea-splitting organisms should be cleared. Evaluation by ultrasonography and serum chemistries is then appropriate once a year. Eventually, yearly endoscopy for tumor surveillance may be performed. No consensus exists about the timing or frequency of cystoscopic examination. Higuchi and coworkers (2010) have suggested that surveillance may

be of greater yield in patient populations at greater risk such as valve patients who are on immunosuppression after transplantation or exstrophy patients with their inherent increased risk for bladder adenocarcinoma. After the report of Castellan and coworkers (2012), surveillance may be of higher yield after gastrocystoplasty. It should be noted that there is no experience that demonstrates that routine surveillance is cost-effective or successful in this population (Higuchi et al, 2011; Kokorowski et al, 2011), and the Mayo Clinic group has gone so far as to suggest that such surveillance be discontinued (Higuchi et al, 2011).

Results and Complications of Augmentation Cystoplasty

The effect of cystoplasty on the patient should be considered in two ways. One must first consider the effect of removing a relatively small portion of the gastrointestinal tract for use in urinary reconstruction. Any more than rare development of gastrointestinal problems would be prohibitive, even if results were perfect from the standpoint of the urinary bladder. Second, the effect of augmentation cystoplasty on the urinary bladder must be reviewed. The primary goal of augmentation is to provide a compliant urinary reservoir. Therefore the main considerations after augmentation are the storage pressure and capacity that are achieved. Any other effects on the urinary bladder are side effects or complications that exist because bowel is not a perfect physiologic substitute for native bladder. It is clear that approximately one third of patients will require further surgery after augmentation cystoplasty because of various problems (Metcalfe et al, 2006; Kispal et al, 2011).

Gastrointestinal Effects

Postoperative bowel obstruction is uncommon after augmentation cystoplasty, occurring in approximately 3% of patients after augmentation (Gearhart et al, 1986; King, 1987; Mitchell and Piser, 1987; Hollensbe et al, 1992; Rink et al, 1995a). The rate of obstruction is equivalent to that noted after conduit diversion or continent urinary diversion (McDougal, 1992b). Delicate handling of tissues, closure of mesenteric windows, and elimination of sites of internal herniation help to avoid obstruction. Occasional series have suggested differing rates of bowel obstruction depending on the segment used. These differences have not been consistent in most series and are therefore likely not significant.

Reports of chronic diarrhea after bladder augmentation alone have been rare. Diarrhea can occur after removal of large segments of ileum from the gastrointestinal tract, although the length of the segments typically used for augmentation rarely is problematic unless other problems coexist. The use of a typical colonic segment for augmentation only rarely results in a change in bowel function. Removal of a segment from the gastrointestinal tract including the ileocecal valve is more likely to cause diarrhea. Some children with neurogenic impairment depend on constipation for fecal continence. Removal of the ileocecal valve from the gastrointestinal tract may significantly decrease bowel transit time. Loss of the valve can also allow bacterial backflow into the ileum, and the organisms may interfere with fat and vitamin B₁₂ metabolism. Studies have noted chronic diarrhea in 10% to 23% of patients with neurogenic dysfunction after displacement of the ileocecal valve (King, 1987; Roth et al, 1995), although the risk may be lower for carefully selected patients (Husmann and Cain, 1999).

Ileum is the sole site of vitamin B₁₂ absorption. Removal of the distal ileum from the gastrointestinal tract may therefore result in vitamin B₁₂ deficiency and megaloblastic anemia. The terminal 15 to 20 cm of ileum should not be used for augmentation, although problems may arise even if that segment is preserved (Steiner and Morton, 1991; Racioppi et al, 1999). Again, the risk is greater if longer segments of ileum are used as with continent diversion. Thirty-five percent of patients followed over 5 years after a Kock pouch procedure were found to be deficient in vitamin B₁₂ in one series (Akerlund et al, 1989). In general, the length of ileum used for augmentation is less than one half that used for a Kock pouch, so vitamin B₁₂ deficiency seems unlikely after routine bladder augmentation. Canning and associates evaluated 26 patients after bladder augmentation or replacement and found no patients with either fat malabsorption or vitamin B₁₂ deficiency (Canning et al, 1989). Only three patients, however, were followed for longer than 3 years, and longer observation is necessary because existing body vitamin B₁₂ storage may last considerably longer (Stein et al, 1997a). VanderBrink and associates (2010) found low or low-normal B₁₂ levels in 41% of patients evaluated a mean of 83 months after ileocystoplasty and were able to increase those levels by giving the oral vitamin.

Early satiety may occur after gastrocystoplasty but usually resolves with time. Disorders of gastric emptying should be extremely rare, particularly when gastric body is used.

Bladder Compliance after Augmentation

An early lesson of past clinical experience with augmentation cystoplasty has been the value of detubularization and reconfiguration of the bowel segment (Hinman, 1988; Koff, 1988). Some surgeons with extensive experience in augmentation cystoplasty have concluded that ileum is superior to other segments in terms of compliance after augmentation, although controlled experimental examination of similarly sized bowel segments is lacking (Goldwasser and Webster, 1986; Rink and McLaughlin, 1994; Studer and Zingg, 1997). On the contrary, one report has suggested superior results with colon compared with ileum (Shekariz et al, 2000) when a longer colonic segment reconfigured in a U shape was used. Good results have been achieved with all segments in most cases, and it is more important to use a bowel segment well than to choose a particular bowel segment for every patient.

Occasional problems with pressure after augmentation cystoplasty occur from uninhibited contractions, apparently in the bowel segment. It is extremely rare not to achieve an adequate capacity or flat tonus limb unless a technical error has occurred with use of the bowel segment. When pressure contractions occur in the bladder after augmentation, they are often noted in a rhythmic or sinusoidal pattern, occasionally with increasing amplitude (Fig. 145-13). Contractions that begin at low amplitude later in filling and progress only near capacity may be of no clinical significance. Early contractions of higher pressure may result in persistent incontinence, delayed perforation, hydronephrosis, or vesicoureteral reflux. If patients have such clinical problems after augmentation, repeat urodynamic testing is indicated because one cannot assume the bladder is compliant after augmentation. Rhythmic contractions have been noted postoperatively with all bowel segments, although ileum seems the least likely to demonstrate remarkable urodynamic abnormalities, and stomach the most.

After bladder augmentation or replacement, some urodynamic evaluation has suggested that colonic segments, whether cecum or sigmoid, still generate more pressure than ileum despite detubularization (Berglund et al, 1987; Jakobsen et al, 1987; Thuroff et al, 1987; Lytton and Green, 1989; Studer and Zingg, 1997), although other work has suggested that pressure contractions from the colon decrease with time (Hedlund et al, 1984; Sidi et al, 1986b). Goldwasser's review of enterocystoplasty demonstrated contractions greater than 15 cm H₂O in 42% of patients after ileocystoplasty versus in 60% of those after colocystoplasty (Goldwasser et al, 1987). Significant contractions, defined as those above 40 cm H₂O at a volume below 200 mL, were not noted in any of the ileal augmentations but persisted in 10% of cystoplasties. Their work agreed with that of Berglund and colleagues (1987) and Studer and Zingg (1997) in suggesting that ileal reservoirs have lower basal pressures and less motor activity. It must be noted that none of these studies critically controlled for the size of the bowel segment or the technique in which they were used. In fact, a canine model of partial bladder replacement using identically sized segments failed to demonstrate in vitro or in vivo differences between the gastrointestinal segments (Nelson et al, 2005).

Rhythmic contractions after gastrocystoplasty have been noted in up to 62% of patients (Adams et al, 1988; Atala et al, 1993; Gosalbez et al, 1993a; Roth et al, 2000). The segment of stomach initially described for augmentation using the body was much smaller in size than segments of ileum or colon commonly used. Use of a larger gastric segment that is longer along the greater curvature results in improved urodynamics after augmentation with less prominent contractions (Adams et al, 1995; Kurzrock et al, 1998; Koraitim et al, 1999; DeFoor et al, 2003a). Leong (1988) has suggested that an antral segment of stomach is less likely to demonstrate such contractions.

In perhaps the most extensive experience with pediatric bladder augmentation, Hollensbe and associates at Indiana University

Figure 145-13. Rhythmic, sinusoidal contractions (*top*) may occur after bladder augmentation, in this case with stomach. Contractions of significant amplitude early in filling occasionally require secondary augmentation. After secondary augmentation with ileum (*bottom*), urodynamics show that contractions still occur but are much lower in pressure and occur later in filling.

found that approximately 5% of patients had significant uninhibited contractions after augmentation cystoplasty causing clinical problems (Hollensbe et al, 1992). Pope and Rink (1999) found that 6% of over 300 patients required secondary augmentation of a previously augmented bladder for similar problems. With longer follow-up, the same group has eventually performed reaugmentation in 9% of patients (Metcalf et al, 2006). These secondary augmentations represent true failures of the cystoplasty to achieve their primary objectives, capacity and compliance. In that series, sigmoid colon followed by stomach and then ileum were more likely to require reaugmentation. It should be noted that a colonic segment closed at the ends and not reconfigured otherwise was typically used in that experience. Other studies have suggested that stomach is more likely than colon to require secondary intervention (El-Ghoneimi et al, 1998; Castellan et al, 2012).

Metabolic Complications

Chloride Absorption and Acidosis. The first recognized metabolic complication related to storage of urine within intestinal segments was the development of hyperchloremic metabolic acidosis after ureterosigmoidostomy (Ferris and Odel, 1950). Patients with this metabolic derangement were noted to have fatigue, weakness, anorexia, and polydipsia. Koch and McDougal (1985) demonstrated the mechanisms by which acid is absorbed from urine in contact with intestinals mucosa. Resorption in the form of ammonium results in chronic acid loading. Patients with normal renal function are usually able to handle the resorbed load of chloride and acid without frank acidosis. Mitchell and Piser (1987) noted that essentially every patient after augmentation with an intestinal segment had an increase in serum chloride and a decrease in serum bicarbonate level, although full acidosis was rare if renal function was normal. Acidosis and electrolyte disturbances requiring treatment have been reported despite normal renal function (Schmidt et al, 1973; Whitmore and Gittis, 1983). Such derangements may be debilitating to the patient if not recognized and treated (Heidler et al, 1979). Hall and colleagues noted that there is an increase in the urinary acid load with wasting of bony buffers even in the absence of frank acidosis (Hall et al, 1991). Such wasting may result in bone demineralization and could potentially cause retarded growth in children after augmentation cystoplasty (Abes et al, 2003; Hafez et al, 2003; Vajda et al, 2003). Patients with acidosis should receive bicarbonate therapy. Nurse and Mundy (1989) have suggested that arterial blood gas values may be more sensitive than serum bicarbonate or chloride levels for detecting acidosis. Stein and associates (1998) felt that measurements of arterial blood gas for base deficit allowed early treatment

of acidosis and avoidance of bone demineralization. In severe cases of acidosis, chloride transport can be blocked with chlorpromazine and nicotinic acid.

Although jejunum is rarely used for bladder reconstruction, storage of urine in this segment results in a unique metabolic pattern of hyponatremic, hypochloremic, and hyperkalemic metabolic acidosis. The problem is often associated with significant hypovolemia.

Gastric mucosa is a barrier to chloride and acid resorption and, in fact, secretes hydrochloric acid (Piser et al, 1987). This difference was the primary factor in the initial consideration of stomach for use in the urinary tract. This secretory nature was shown to be of benefit in azotemic animals during acid loading (Piser et al, 1987; Kennedy et al, 1988). Serum chloride does decrease and serum bicarbonate increase slightly after gastrocystoplasty whether antrum or body is used in patients with normal and impaired renal function (Adams et al, 1988; Ganesan et al, 1991; Kurzrock et al, 1998). In 21 patients with renal insufficiency, serum bicarbonate improved in all patients except 1 after gastrocystoplasty, and many patients requiring oral bicarbonate therapy before cystoplasty did not do so after gastrocystoplasty (Ganesan et al, 1991). A similar benefit was noted in a group of patients with renal failure (Sheldon and Gilbert, 1991).

Patient Growth. Delayed or slowed growth in some children after intestinal cystoplasty has previously been recognized (Wagstaff et al, 1991; Mundy and Nurse, 1992; Wagstaff et al, 1992). A delay in linear growth was noted in 20% of almost 200 pediatric patients without any gross biochemical abnormalities. However, no control patients were included in that series. Body habitus and growth are difficult to predict in children with myelodysplasia, who make up the majority in most series of augmentation cystoplasty. Gros and colleagues (2000) evaluated growth in exstrophy patients. Patients requiring augmentation were matched retrospectively with a similar group not requiring bladder augmentation. Only 1 patient was noted to have acidosis in either group. Other factors that might affect growth, such as urinary tract infection, were not controlled. Of 17 patients with adequate measurements before and after cystoplasty, 14 (82%) had a decline in percentile height postoperatively. The decline corresponded to a 1½-inch decrease in expected height. The pattern of growth was significantly different between patients with and without augmentation in the series. That series is small, and no evaluation of familial growth patterns or ultimate height was possible; however, the findings are worrisome, particularly because Feng and colleagues (2002) noted similar differences in exstrophy patients. In the absence of any serum abnormalities, the exact mechanism of delayed growth was not evident, although it seems likely to be related to subclinical acidosis (Koch and

McDougal, 1988; Bushinsky, 1989; Hochstetler et al, 1997). It should be noted that Taskinen and colleagues (2008) found no adverse effect on longitudinal growth after bladder augmentation in the exstrophy population.

Three recent series did show effect of bowel cystoplasty on bone mineral density in some patients (Abes et al, 2003; Hafez et al, 2003; Vajda et al, 2003), whereas two others did not (Mingin et al, 2002; Haas et al, 2012). One must be careful to determine whether any such changes are the result of augmentation cystoplasty or the underlying pathology (Boylu et al, 2006; Taskinen et al, 2007; Haas et al, 2012). Better analysis of subtle metabolic alterations after enterocystoplasty may establish better understanding of the effect on growth, minimize changes, or aid in early treatment to avoid the complication (Brkovic et al, 2004).

Alkalosis. The secretory nature of gastric mucosa may at times be detrimental to the patient and can result in two unique complications of gastrocystoplasty. Episodes of hypokalemic, hypochloremic metabolic alkalosis after acute gastrointestinal illnesses were noted in 5 of 37 patients following gastrocystoplasty (Hollensbe et al, 1992). The episodes were significant enough to require hospitalization in all patients and were recurrent in 2 patients. Three of the 5 patients who developed the complication had renal insufficiency and would not have been good candidates for augmentation with other segments owing to acidosis. Ganesan and associates noted similar episodes of alkalosis in 5 of 21 patients with renal insufficiency after gastrocystoplasty (Ganesan et al, 1991). Patients with the primary indication for consideration of gastrocystoplasty may be the ones at greatest risk for this unusual complication. It has been proposed that the alkalosis results from ongoing chloride loss from the gastric segment in the bladder in the face of decreased oral intake. Gosalbez and associates (1993b) demonstrated persistently increased fractional excretion of chloride despite profound hypochloremia, suggesting that inappropriate gastric secretion is likely the primary mediator. One patient in their series eventually required resection of three quarters of the gastric segment in the bladder because of recurrent problems with alkalosis, and several required therapy with H₂ blockers or H⁺/K⁺ ion pump inhibitors. All patients and families should be made aware of this potential problem because it has been reported to occur intermittently in 3% to 24% of patients. A composite reservoir of stomach and ileum or colon may provide a more metabolically neutral reservoir (McLaughlin et al, 1995; Austin et al, 1997, 1999, 2001), although these have typically been constructed in only very complex patients or circumstances.

Hematuria-Dysuria Syndrome. Acid secretion by gastric mucosa may result in another unique problem after gastrocystoplasty, the hematuria-dysuria syndrome. Mitchell's group characterized this syndrome well (Nguyen et al, 1993; Plaire et al, 1999). Virtually all patients after gastrocystoplasty with normal sensation have occasional hematuria or dysuria with voiding or catheterization beyond what is expected with other intestinal segments (Leonard et al, 1999). All patients should be warned of this potential problem, although in most patients these symptoms are intermittent and mild and do not require treatment. The problem led one group to recommend avoiding gastrocystoplasty in patients with bladder exstrophy (El-Ghoneimi et al, 1998). The dysuria is not as problematic in patients with neurogenic dysfunction. In the experience of Nguyen and colleagues (1993), 36% of patients developed signs or symptoms of the hematuria-dysuria syndrome after gastrocystoplasty. Fourteen percent of patients required treatment with medications, including 9% on a regular basis. Patients who are incontinent or have decreased renal function are at increased risk. Others have noted a similar requirement for short-term and chronic medical therapy (Hollensbe et al, 1992; Adams et al, 1995; Castellan et al, 2012). The symptoms of the hematuria-dysuria syndrome do respond well to H₂ blockers and hydrogen ion pump blockers. Bladder irrigation with baking soda may also be effective. It has been demonstrated that urinary pH may decrease remarkably after meals in patients who have undergone gastrocystoplasty (Bogaert et al, 1995). The signs and symptoms of the hematuria-dysuria syndrome are most likely secondary to acid irritation. Work has

suggested that *Helicobacter pylori* may play a role in this complication (Celayir et al, 1999). Such problems can occur but are less frequent after antral cystoplasty because there is a smaller load of parietal cells (Ngan et al, 1993).

Acid in the urine may also cause external irritation. Leong first noted glanular excoriation after gastrocystoplasty in a patient with voiding symptoms (Ngan et al, 1993). Nguyen and associates noted skin excoriation in 8 of 57 patients following gastrocystoplasty; all 8 patients had some element of urinary incontinence (Nguyen et al, 1993). It is imperative to achieve reliable urinary continence in patients undergoing gastrocystoplasty because urinary leakage may result in the exposure of the skin to gastric secretions and in gastric secretions that are poorly diluted. Dilution is important; Reinberg and coworkers reported a perforation of a gastric segment in a defunctionalized bladder after gastrocystoplasty (Reinberg et al, 1992). They evaluated the influence of urine on gastrocystoplasties in dogs (Castro-Diaz et al, 1992). The animals developed marked inflammation of the gastric segment and native bladder after creation of a dry gastrocystoplasty; three of nine dogs developed ulceration and perforation. Use of H₂ blockers resulted in some protection for the animals; however, such a clinical situation should certainly be avoided. Rare perforations and ulcerations have been noted clinically without defunctionalization (El-Ghoneimi et al, 1998; Mingin et al, 1999a).

Mucus

Intestinal segments continue to produce mucus after placement in the urinary tract. The material can potentially impede bladder drainage during voiding or CIC, particularly in pediatric patients in whom the use of small-caliber catheters is necessary. Mucus may serve as a nidus for infection or stone formation when it remains in the bladder for long periods of time. Mucus production often increases after cystoplasty in the presence of cystitis. Kulb and associates (1986) showed experimentally in dogs that colonic segments produce more mucus than ileum and that gastric segments produce the least amount. This has been noted clinically as well; most patients do not require any routine bladder irrigations for mucus after gastrocystoplasty. Villous atrophy in the ileum has been documented after placement in the urinary tract. It has been suggested that such atrophy may result in decreased mucus production (Gearhart, 1987), although laboratory demonstration of any decrease in production with time has not been evident (Murray et al, 1987). Hendren and Hendren (1990) noted a decrease in mucus production from colonic segments over years; however, others have not been impressed with such changes (Rink et al, 1995a). Glandular atrophy in colonic mucosa has not been noted histologically (Mansson et al, 1984). Routine use of daily bladder irrigations to prevent mucus buildup may minimize complications of enterocystoplasty such as urinary tract infection and calculi (Hensle et al, 2004).

Urinary Tract Infection

Bacteriuria is common after intestinal cystoplasty, particularly in patients requiring intermittent catheterization (Gearhart et al, 1986; Hendren and Hendren, 1990; King, 1991). Recent experience with bowel neobladders has demonstrated that patients who are able to spontaneously void to completion often maintain sterile urine. It appears that use of CIC is a prominent factor in the development of bacteriuria in patients who have undergone augmentation cystoplasty. Bacteriuria has been noted even when patients are maintained on daily oral antibiotics or antibiotic irrigation (Gearhart et al, 1986; Casale et al, 1999). In Hirst's (1991) experience, persistent or recurrent bacteriuria occurred in 50% of patients augmented with sigmoid colon versus 25% of those following ileocystoplasty. Hollensbe and coworkers noted bacteriuria much more commonly in patients requiring CIC regardless of the segment considered (Hollensbe et al, 1992). The incidence of symptomatic cystitis after cystoplasty likely depends on the length of follow-up and the diligence with which symptoms are sought.

All patients and families should be told to expect some signs or symptoms of cystitis. Recurrent episodes of symptomatic cystitis requiring treatment occurred in 23% of patients after ileocystoplasty, 17% of patients after sigmoid cystoplasty, 13% after cecocystoplasty, and 8% after gastrocystoplasty at Indiana University (Hollensbe et al, 1992). Febrile urinary tract infections occurred in 13% of those 231 patients after augmentation. The same trend among different bowel segments was noted for febrile infections, although there was no statistically significant difference among the various segments. **The incidence of pyelonephritis after augmentation cystoplasty, as long as upper tract problems are corrected, is quite similar to that noted for conduit diversion, whether refluxing or not (McDougal, 1992b).** Infections may occasionally be more problematic in an immunocompromised patient (Alfrey et al, 1997), but that has not always proven to be the case (Traxel et al, 2011).

Not every episode of asymptomatic bacteriuria requires treatment in patients performing CIC. Bacteriuria should be treated in the presence of significant symptoms such as incontinence or suprapubic pain and may be treated if hematuria, foul-smelling urine, or remarkably increased mucus production occurs. **Bacteriuria should be treated if the urine culture demonstrates growth of a urea-splitting organism that may lead to stone formation.** To minimize infection, patients requiring CIC must perform it on a regular basis to avoid increased reservoir pressures and must work to empty the bladder completely. Special care must be taken by patients catheterizing through a continent abdominal wall stoma. Such patients may have more difficulty completely emptying the bladder from a nondependent stoma. Most can do so with effort (Ludlow et al, 1995). Although catheterization is not routinely a sterile technique, use of proper clean technique should be emphasized.

Calculi

Another long-term complication of augmentation cystoplasty is bladder calculus formation. In the early 1990s, several series reported calculi in 18% of patients after augmentation cystoplasty (Hendren and Hendren, 1990; Hirst, 1991). Blyth and associates noted calculus formation in 30% of such patients; they found that patients catheterizing through an abdominal wall stoma have the highest risk, likely because of incomplete emptying (Blyth et al, 1992). Palmer and colleagues (1993) noted urolithiasis in 52% of patients after augmentation cystoplasty. Metcalfe and colleagues (2006) noted a 15% rate of bladder stone formation in 500 patients with long-term follow-up after enterocystoplasty; the reasons for these remarkable differences are not clear. **Most bladder stones in this patient population are struvite in composition, and bacteriuria is an important risk factor.** Any infection with a urea-splitting organism should therefore be treated. All patients requiring CIC, particularly those who have already formed stones, should make every effort to empty the bladder completely with each catheterization. If stones are found in patients voiding spontaneously after augmentation, the adequacy of emptying should be re-evaluated. The association of urinary stasis with stone formation is well established. Routine bladder irrigations to avoid buildup of inspissated mucus may remove a nidus for stone formation. The group at Indiana and others have stressed irrigations and asked patients and families to routinely irrigate the bladder several times a day after augmentation (Rink et al, 1995a; Hensle et al, 2004). Stones have been noted after the use of all intestinal segments with no significant difference noted between small and large intestine. Struvite stones are less likely after gastrocystoplasty (Kaefer et al, 1998; Kronner et al, 1998a), likely because of decreased mucus production and acid that minimizes bacteriuria. Uric acid calculi have been noted in the bladder after gastrocystoplasty (Kaefer et al, 1998). Clearly, any foreign body will serve as a nidus for stone formation; the use of permanent sutures or staples in the urinary tract should be avoided during enterocystoplasty. Khoury and associates (1997) looked for metabolic problems in patients after augmentation and noted low urinary citrate levels in patient with and without stones.

They thought that poor emptying and mucus were more significant factors.

Tumor Formation

A well-recognized complication of ureterosigmoidostomy has been the development of tumors, primarily adenocarcinoma, at the ureterocolonic anastomotic site. In Husmann and Spence's (1990) review of reported tumors after ureterosigmoidostomy, the latency for development of such tumors averaged 26 years and ranged from 3 to 53 years. Adenocarcinomas were the prominent tumors that developed, but benign polyps and other types of carcinoma were also found. Eraklis and Folkman (1978) estimated that the risk for developing such tumors is increased by 7000-fold over age matched controls after ureterosigmoidostomy. Pettersson and colleagues (2013) reviewed their experience with 24 patients who had undergone ureterosigmoidostomy from 1944 to 1961; most had eventually been undiverted. Invasive colorectal adenocarcinoma developed in 7 patients, 5 of whom died as a result. The risk for tumor formation was 42 times that of the general Swedish population.

The basis for the increased risk is unknown; however, *N*-nitroso compounds thought to originate from a mixture of urine and feces may be carcinogenic. These compounds have been noted in the urine of patients with conduit diversion and augmentation (Treiger and Marshall, 1991). Husmann and Spence (1990) suggested that those compounds are more likely enhancing agents rather than a lone cause for tumor development. It has been proposed that inflammatory reaction at the anastomotic site may induce growth factor production, which, in turn, increases cellular proliferation. Filmer and Spencer (1990) identified 14 patients who have developed adenocarcinoma in an augmented bladder, and several more have been reported since then. Nine of those tumors occurred after ileocystoplasty, and 5 after colcystoplasty. One study has noted a relatively high incidence of tumor after gastrocystoplasty (Castellan et al, 2007). Experimental work in the rat demonstrated hyperplastic growth in the augmented bladder using all intestinal segments, with no segment showing any particular increased risk (Klee et al, 1990; Buson et al, 1993; Spencer et al, 1993; Little et al, 1994; Kispal et al, 2012). The long latency noted for tumor development after ureterosigmoidostomy suggests that short-term follow-up after augmentation cystoplasty is not adequate to evaluate tumor formation. The earliest reported tumor after augmentation was found only 4 years after cystoplasty (Carr and Hershow, 1997). **Patients undergoing augmentation cystoplasty should be made aware of a potential increased risk for tumor development.** Yearly surveillance of the augmented bladder with endoscopy may eventually be performed; the latency period until such procedures are necessary is not well defined (Vajda et al, 2002; Higuchi et al, 2011). Transitional cell carcinoma, hyperplasia, and dysplasia have also been noted near the anastomosis in humans (Gregoire et al, 1993; Barrington et al, 1997; Soergel et al, 2004). Transitional cell carcinomas associated with augmentation cystoplasty have been aggressive; often the patients have metastatic disease at presentation (Metcalfe et al, 2006; Higuchi et al, 2010). Urothelium adjacent to the anastomosis was demonstrated to be genetically unstable on biopsy in one study (Appanna et al, 2007). Castellan and associates (2012) noted a sobering experience with three cases of fatal adenocarcinoma within the gastric segment among only 29 patients who had undergone gastrocystoplasty. A benign lesion, nephrogenic adenoma, may actually be the most common tumor found after cystoplasty (Franke et al, 2011).

Delayed Spontaneous Bladder Perforation

Another disturbing complication of augmentation cystoplasty is delayed bladder perforation. Patients with spontaneous perforation after augmentation cystoplasty are typically quite ill with abdominal pain, distention, and fever. Sepsis has been common. Nausea, decreased urine output, and shoulder pain from diaphragmatic irritation have also been noted. Perforations have been found in

Figure 145-14. After complete filling, a sagittal view on the cystogram demonstrates a spontaneous bladder perforation on the post-drain view.

evaluation of asymptomatic pelvic masses (Pope et al, 1999) (Fig. 145-14). Patients with neurogenic dysfunction often have impaired lower abdominal sensation and are seen later in the course of the illness; severe sepsis and death have occurred. Patients with perforation after gastrocystoplasty often seek care promptly because of acid irritation. A high index of suspicion for perforation is necessary. Contrast cystography is diagnostic in most cases (Braverman and Lebowitz, 1991; Rosen and Light, 1991; Bauer et al, 1992) (see Fig. 145-14). Thorough technique is important to identify as many true positives as possible with cystography (Braverman and Lebowitz, 1991). Some reports have noted a significant false-negative rate on cystography (Rushton et al, 1988; Sheiner and Kaplan, 1988; Pope et al, 1999) and suggested that ultrasonography and computed tomography improve diagnostic accuracy. They recommended that one of those studies be done in any child suspected to have a perforation if the initial cystogram is negative.

Etiology. The cause of delayed perforations within a bowel segment is unknown. It has been suggested that some perforations might be secondary to traumatic catheterization (Elder et al, 1988; Rushton et al, 1988). Perforation of a bladder not previously augmented has been recognized after CIC (Reisman and Preminger, 1989). It seems unlikely that catheterization trauma is the lone cause in most patients. The location of the perforations has been variable among patients and even in a single patient with multiple perforations. Perforations have occurred in patients after augmentation who did not catheterize at all. Other authors have suggested that trauma to the bowel because of fixed adhesions resulting in sheering forces with emptying and filling may result in perforation (Elder et al, 1988). Transmural infection of the bladder wall has also been proposed as a cause. Histologic examination of areas of perforation has noted necrosis, vascular congestion, hemorrhage, and hemosiderin deposition compatible with chronic bowel wall ischemia (Crane et al, 1991). Chronic over distention of the bladder might result in such ischemia. Decreased perfusion in dog bowel used for augmentation can be induced experimentally with high intravesical pressure (Essig et al, 1991); changes were noted more prominently at the antimesenteric border of the bowel. Anderson and Rickwood (1991) have reported perforations occurring in bladders with significant uninhibited contractions after augmentation, as have others (Pope et al, 1998). High outflow resistance may maintain bladder pressure rather than allowing urinary leakage and venting of the pressure, potentially increasing ischemia (Martinez del Castillo et al, 2005). Hyperreflexia alone is likely not a solitary cause of perforation; the complication was not recognized in the era before bowel detubularization and reconfiguration when persistent pressure contractions were more

common. Once bowel is reconfigured, however, it may be more prone to ischemia if high pressure does persist. Failure to perform CIC on a regular basis when needed to empty may exacerbate such issues (DeFoor et al, 2003b; Martinez del Castillo et al, 2005).

The majority of patients who develop perforations after augmentation cystoplasty have had myelodysplasia. The incidence of perforation has been lower in series of patients with other diagnoses requiring bladder reconstruction (Hendren and Hendren, 1990). The role of neurogenic dysfunction in the cause of these perforations is unclear. No matter what the cause, there is likely some field effect on the entire segment. Once a patient has sustained a spontaneous perforation, the chance of recurrence is significant (Hollensbe et al, 1992; Martinez del Castillo et al, 2005), perhaps occurring in one quarter of patients (Metcalf et al, 2006). Consideration must eventually be given to removal of the original segment and replacement with another after repeated perforation.

Incidence. Early postoperative leaks from the bowel-to-bowel or bowel-to-bladder anastomoses after augmentation cystoplasty are rare and represent a technical error or problem with early healing. Delayed perforations more commonly occur within the bowel segment itself and represent a problem with long-term storage of urine within an intestinal segment. There may be no particular increased risk of one intestinal segment over another. At Indiana University, perforations were noted in 43 of 500 patients (8.6%) undergoing cystoplasty (Metcalf et al, 2006) an average of 4.3 years after augmentation. Analysis of this experience suggested that the use of sigmoid colon was the only significantly increased risk factor. Several other large series of patients with sigmoid cystoplasty have noted a low incidence of delayed perforation (Sidi et al, 1987a; Hendren and Hendren, 1990; Shekarriz et al, 2000). At Children's Hospital (Boston), the incidence of perforation after augmentation was reportedly highest in ileum (9.3%) and less frequent in ileocecal, sigmoid, and gastric segments (Bauer et al, 1992). With inconsistent differences across multiple large series, it is unlikely that any given enteric segment is at significantly increased risk for perforation and that multiple factors influence the risk for the complication. The highest rate of perforation noted was 16.6% in one relatively small series (Martinez del Castillo et al, 2005); however, it is reasonable to present an expected risk of about 9% to patients and families based on experience at Indiana University (Metcalf et al, 2006).

Treatment. The standard treatment of spontaneous perforation of the augmented bladder is immediate surgical repair. There are reported series of conservative management for suspected perforation (Slaton and Kropp, 1994). Conservative management including catheter drainage, antibiotics, and serial abdominal examinations was successful in 87% of patients, although only 2 of the 13 patients with suspected ruptures had x-ray documentation unequivocally identifying a perforation. Even patients who do well with conservative management during the acute episode often require eventual surgical intervention (Pope et al, 1999). Such management may be a consideration in a stable patient with sterile urine, but there should be a very low threshold for surgical repair. Most patients with perforations have myelodysplasia and are seen late in the course of the disease owing to impaired sensation. Increasing sepsis and death of the patient may result from a delay in diagnosis or treatment.

Pregnancy

Limited information exists regarding the outcome of pregnancy in women who have undergone augmentation cystoplasty. Three issues are raised in the context of pregnancy after bladder reconstruction: how the expanding uterus will affect the pedicle of the reconstruction; how to manage bacteriuria in the setting; and whether cesarean section is necessary in all or some patients.

Hatch and colleagues (1991) and Schumacher and colleagues (1997) noted that the mesenteric pedicle to bladder augmentations did not appear to be stretched at the time of cesarean section. In those cases the pedicle was not located near the exposed anterior uterus but deflected laterally. Schilling and colleagues

(1996) recognized similar deflection away from the uterus after urinary diversion but did occasionally find the uterus covered by the vascular pedicle after bladder augmentation. Neither process prevented the rise of the uterus during pregnancy. Those authors speculated that the mesentery underwent changes that enabled deflection or stretch without any adverse effect on circulation. Loss of the augmentation from a mechanical effect on the pedicle from the enlarging uterus has not been reported. Pregnancy itself has not been reported to have a detrimental effect on the augmentation other than temporary incontinence in some patients, particularly during the last trimester.

Urinary tract infections may be problematic during pregnancy in women who have undergone urinary reconstruction including bladder augmentation. Ureteral dilation, increased residual urine, and diminished tone to the upper tract may all be important risk factors (Hill et al, 1990; Hatch et al, 1991). Asymptomatic bacteriuria is usually treated immediately in pregnant women because of an increased rate of progression to symptomatic infection and pyelonephritis and because of the potentially significant consequences of pyelonephritis. There is little consensus about the role of antibiotics and the risk of asymptomatic bacteriuria in women on CIC after cystoplasty once pregnant (Thomas and Adams, 2009). Antibiotics, if used, must not be teratogenic.

Successful pregnancy with spontaneous vaginal delivery has been observed in some patients with bladder augmentations (Quenneville et al, 2003) and other forms of urinary reconstruction (Pedlow, 1961; Asif and Uehling, 1969). Schumacher and colleagues (1997) reviewed their experience with pregnancy and delivery in patients who had undergone continent catheterizable ileocecal diversion and found no major complications. This would likely be true for other forms of reconstruction (Wren et al, 2003). Late difficulty with catheterization has been noted with Kock continent ileostomies (Ojerskog et al, 1988) and can occur with any continent abdominal wall stoma (Greenwell et al, 2003).

The need for cesarean section is likely not universal after bladder reconstruction. Flaccid, distensible pelvic tissues, perhaps necessary for progression to spontaneous vaginal delivery, may not be present after extensive pelvic surgery. It is not known if tissues fixed from previous operative repairs can undergo the trauma of delivery and resume the same level of function found before the pregnancy. Our bias would be that woman having undergone extensive bladder neck repair should consider cesarean delivery, particularly if the progression toward spontaneous vaginal delivery is slowed or difficult at all. Although there are reports of spontaneous vaginal delivery in the presence of an AUS (Fishman and Scott, 1993; Creagh et al, 1995), the presence of such a prosthetic device raises a concern for erosion with a long, difficult delivery.

If cesarean section is required or selected, it is imperative to protect the augmentation or continent stoma and its vascular pedicle. The anterior uterus can typically be exposed atraumatically, although some time and patience may be required to protect the bladder. Such exposure may be more difficult if multiple abdominal stomas are present. The reconstructive urologist familiar with the patient and her anatomy should be present during cesarean section.

Choice of Segment and Approach

Enterocystoplasty improves bladder capacity and compliance in most cases when medical management fails. It is obvious from the previous discussion that there is no one single bowel segment that is perfect for augmentation in all patients. All gastrointestinal segments have been used and continue to be used with good results. Unremitting medical problems are relatively rare after augmentation cystoplasty if used appropriately in well-selected patients. No one bowel segment has a clear advantage over others when all such problems are considered. Patient diagnosis, anatomy, and physiology may suggest that one bowel segment is preferable for a particular patient. Each surgeon interested in augmentation cystoplasty should be familiar with the advantages and disadvantages of each segment in different settings.

In many routine cases, any gastrointestinal segment may be chosen for cystoplasty based purely on the personal preference and familiarity of the surgeon. The surgeon's experience and confidence in using a segment are important. **We believe that no one bowel segment is the best choice in all patients and that optimal results are achieved when the bowel segment is chosen based on the needs of the particular patient. The segment must then be used correctly.** Ileum is preferred if there is no clear advantage or reason to use another segment. Stomach is reserved for very select children with renal insufficiency and acidosis, short gut syndrome, and heavy irradiation; even then, the potential complications of gastrocystoplasty must be considered (Castellan et al, 2012). Sigmoid cystoplasty is used in select patients without reservation; good results can be expected for most patients with any segment if it is used properly.

The use of laparoscopy, usually with robotic assistance, to achieve augmentation cystoplasty evolved from early work on auto-augmentation to full intracorporeal enterocystoplasty (Ehrlich and Gershman, 1993; Docimo et al, 1995; Lorenzo et al, 2007; Gundeti et al, 2008). Intraoperative times vary greatly among these reports and are related to surgeon experience and inherent patient factors such as prior surgery, working space availability, and whether a pure laparoscopic or robotic-assisted approach is used. Outcomes have been similar to those of open reconstruction in early follow-up (Traxel et al, 2010; Gundeti et al, 2013). Potential advantages of a minimally invasive approach include faster recovery and improved cosmesis (Hasan et al, 2011). Experience with these approaches is already accumulating rapidly, and thorough evaluation will be needed to determine if a minimally invasive approach is cost-effective, particularly in the neurogenic population.

A Decreasing Necessity?

Although augmentation cystoplasty works well for most patients who require it and although work on alternatives to bowel cystoplasty may lower morbidity for the patient, a primary goal for every pediatric urologist is to minimize the number of patients needing cystoplasty. Newer medical regimens, botulinum toxin A injections (Schulte-Baukloh et al, 2005; Altaweel et al, 2006; Game et al, 2009; Stoehrer et al, 2009; Pascali et al, 2011), and neuromodulation may prove effective for some patients who at present do not respond to conservative measures (Aslan and Kogan, 2002; Lansen-Koch et al, 2012). Xiao and others (2005; Peters et al, 2010) continue to refine an artificial somatic-autonomic reflex pathway in children with neurogenic dysfunction. No matter what the diagnosis, earlier and more aggressive treatment of bladder dysfunction may minimize the insult to the bladder and maximize recovery as well as ultimate bladder function. Early urodynamic evaluation of boys with posterior urethral valves may identify treatable bladder problems and improve the prognosis from the standpoint of the kidneys and bladder (Misseri et al, 2002; Casey et al, 2012). Grady and associates (2003) suggested that complete primary repair of bladder exstrophy results in early bladder cycling that improves eventual bladder function and decreases the likelihood of augmentation cystoplasty.

With perhaps the most compelling evidence to date, Kaefer and colleagues (1999a) found that only 17% of patients with hostile neurogenic bladder dysfunction treated immediately on diagnosis required augmentation cystoplasty as compared with 41% of similar patients treated expectantly. Although the series included no collaborative urodynamic data and might be subject to lag time bias, the authors felt that there was a significant difference in the outcomes for the two groups. Because there are no prospective, randomized trials evaluating early evaluation and treatment of pediatric bladder dysfunction, suggestions that expectant treatment may lower the necessity for augmentation cystoplasty (Bauer, 2003; Mitchell, 2003) remain unproven. On early examination, early bladder management had not decreased the rate of augmentation cystoplasty (Lendvay et al, 2006); however, more recent re-evaluation (Schlomer et al, 2013) suggested that augmentation rates have fallen by 25% in the past decade. Critical, prospective evaluation of

such treatment is needed and will hopefully demonstrate how to successfully manage these patients. It is likely that such improvements will minimize the need for cystoplasty but not completely remove it (Cain and Rink, 2010).

Improving Quality of Life?

Reconstruction to achieve continence has been assumed to improve health-related quality of life. Early evaluation of small numbers of patients undergoing reconstruction including augmentation cystoplasty does not always show improved status on objective questionnaires compared with preoperative studies or control patients without surgery despite what generally would be considered to be good clinical results (MacNeily et al, 2005; Parekh et al, 2006). Assessment of the social impact of using a catheterizable channel instead of urethra is limited (Kari et al, 2013). Patient-reported scores also do not always correlate with those noted by their parents. Most evaluation of surgical techniques to date has focused on results and complications from the perspective of surgeons. Future evaluation should include objective, patient-reported consideration. Tools to acquire that information must be validated for longitudinal study of these patients and their disease processes.

KEY POINTS: AUGMENTATION CYSTOPLASTY

- Any gastrointestinal segment should be reconfigured and widely anastomosed to the bladder to maximize capacity and compliance.
- Failures to achieve adequate compliance are rare (5% to 10%) and are usually related to rhythmic pressure contractions.
- Gastrointestinal effects are rare, although chronic diarrhea may occur if the ileocecal segment is used in the neurogenic population.
- Ammonium resorption can cause metabolic acidosis, particularly among patients with renal insufficiency.
- Bacteriuria is common after cystoplasty and does not always require treatment.
- Bladder calculi occur in 10% to 30% of patients after augmentation.
- Aggressive adenocarcinomas have been reported as early as 4 years after augmentation but thus far have not occurred with the frequency noted after ureterosigmoidostomy.
- Delayed perforation of the bowel segment can be expected in 5% of patients after augmentation. It has occurred most frequently in colonic segments used in the neurogenic population.
- Good early care for underlying bladder dysfunction may lower the need for augmentation cystoplasty.

Alternatives to Gastrointestinal Cystoplasty

Largely because of the complications just reviewed, alternative methods that can achieve a large-capacity, compliant reservoir remain attractive. Efforts have covered the spectrum from synthetic materials and autologous grafts through creation of a bladder diverticulum (autoaugmentation) to various forms of neural stimulation. Some of these alternatives appear to hold promise, but none have stood the test of time in comparison to intestinal cystoplasty.

An ideal tissue for increasing capacity and improving compliance would have transitional epithelium so as to be relatively impermeable and avoid metabolic changes. The lining would also not produce mucus and would carry no increased potential for tumor development. Two such alternative procedures are ureterocystoplasty and autoaugmentation. With ureterocystoplasty, there is good muscle backing to transitional epithelium, whereas collagen eventually backs the transitional mucosa of an autoaugmentation.

Ureterocystoplasty

It has been noted for years that in patients with posterior urethral valves, unilateral reflux may behave as a pop-off valve to lower intravesical pressures and protect the contralateral upper tract (Hoover and Duckett, 1982; Rittenberg et al, 1988; Kaefer et al, 1995). It was a logical extension to use ureteral tissue in that setting to augment the bladder.

Technique. Ureterocystoplasty may be performed through a midline, intraperitoneal incision. This incision provides access to the intestine should mobilization of the ureter for augmentation be unsatisfactory. Bellinger (1993), Dewan and colleagues (1994), and Reinberg and colleagues (1995) have shown that ureterocystoplasty can be done through two incisions, remaining completely extraperitoneal. The general technique is the same. A standard nephrectomy is performed with great care to preserve the renal pelvic and upper ureteral blood supply. All adventitia and periureteral tissue are swept from the peritoneum toward the ureter during mobilization to protect the ureteral blood supply. Proximally, this blood supply typically arises medially. As the ureter enters the true pelvis, the blood supply arises posterior and laterally. After mobilization of the ureter into the pelvis, the bladder is opened in the sagittal plane. Posteriorly, this incision has typically been carried off-center directly into and through the ureteral orifice of the ureter used for cystoplasty. The ureter is *not* detached from the bladder but is opened longitudinally along its entire length, taking care to avoid its main blood supply (Fig. 145-15). The incision in the bladder and distal ureter should avoid branches of the superior vesical artery, which serves as an important blood supply to the mobilized ureter. The ureter is folded on itself, and the ureter-to-ureter and ureter-to-bladder anastomosis is performed with running absorbable suture. A suprapubic tube is left indwelling through the native bladder for 3 weeks during healing. After cystography documents the absence of leakage, CIC is started. Any patient attempting to void must prove that he or she can empty adequately through a check of postvoid residuals.

Alternatively, the bladder incision can be stopped approximately 2 cm from the orifice, and a similar length of distal ureter left in situ and intact without incision. The resulting small loop of intact ureter does not create clinical problems or adversely affect the end volume in a significant manner (Adams et al, 1998). This modification of technique is easier and may be safer in that it avoids potential injury to the blood supply of the ureter.

Results. Early experience with the procedure noted that the entire renal pelvis could be preserved, allowing more tissue for cystoplasty (Churchill et al, 1993; Landau et al, 1994; McKenna and Bauer, 1995; Reinberg et al, 1995). As with intestinal cystoplasty, folding the ureter into a more spheric configuration maximizes the volume to be achieved. If a massively dilated ureter drains a functioning kidney, the distal ureter alone may be used for augmentation, with the proximal ureter either reimplanted into the bladder or anastomosed to the contralateral ureter (Bellinger, 1993). Numerous series have reported good results after augmentation using ureter, some with follow-up as long as 8 years. The upper tracts have remained stable or improved in virtually all patients. Complications have been uncommon. Landau and colleagues (1994) compared age-matched and diagnosis-matched children undergoing ureterocystoplasty or ileocystoplasty. The total mean bladder capacity was 470 mL in the ureterocystoplasty group and 381 in the ileocystoplasty group. Bladder volumes at 30 cm H₂O were 413 mL and 380 mL after ureterocystoplasty and ileocystoplasty, respectively. Ureter effectively enhanced both volume and compliance. There was one failure in the group, which occurred in a child in whom the distal ureter did not provide enough volume. Work has shown that one dilated ureter typically is enough for cystoplasty (Zubieta et al, 1999; Kajbafzadeh et al, 2010).

The main disadvantage to ureterocystoplasty is the limited patient population with a nonfunctioning kidney draining into a megaureter. McKenna and Bauer (1995) reported the use of a normal-sized ureter. The ultimate success of ureterocystoplasty using normal ureter requires further follow-up, particularly because

Figure 145-15. Ureterocystoplasty. A, After nephrectomy, the bladder is bivalved, with the posterior aspect of the incision carried off the midline to enter the ureteral orifice. The ureter is not detached from the bladder. B, The ureter is opened opposite its main blood supply. C, The ureter is reconfigured as in intestinal cystoplasty before anastomosis to the bladder.

Gonzalez (1999) stated that in one quarter of his patients with posterior urethral valves, ureterocystoplasty with a dilated ureter has failed owing to their huge urinary volume. Husmann and colleagues (2004) noted even worse results if the ureter used was less than 1.5 cm in diameter. Atala and colleagues (1994) presented an experimental technique to slowly dilate a normal ureter for later use. Work continued in porcine models (Stifelman et al, 1998; Desai et al, 2003); however, the principle has not yet proven to be clinically feasible.

Autoaugmentation

Techniques and Results. Cartwright and Snow (1989a, 1989b) described a method to improve bladder compliance and capacity through use of native urothelial tissue. In their procedure, known as *autoaugmentation*, they excised the detrusor muscle over the dome of the bladder, leaving the mucosa intact to protrude as a wide-mouthed diverticulum. Initially they made a midline incision through the bladder muscle (Fig. 145-16A). With the bladder distended with saline so that mucosa bulged from the incision, the muscle was then mobilized and excised laterally in each direction (Fig. 145-16B). The lateral edges of the detrusor muscle were then secured to the psoas muscle bilaterally to prevent collapse of the diverticulum (Fig. 145-16C). Their early experience noted improved compliance in most and increased capacity in some patients (Cartwright and Snow, 1989a).

This procedure has since been modified by a number of surgeons, each applying a different name for the procedure depending on whether the detrusor muscle was simply incised or was excised to create the diverticulum. In an effort to determine if incision or excision provided superior results, Johnson and colleagues performed 16 vesicomytomies and 16 vesicomytectomies in rabbits after previously reducing bladder capacity (Johnson et al, 1994). Functional bladder capacity in the animals increased by 43.5%, and there was no statistical difference between the two techniques. They then performed vesicomytomies (incision) in 12 patients with neurogenic bladder dysfunction and demonstrated a mean increase in capacity of 40% (Stothers et al, 1994). They concluded that detrusor excision offered no advantage over incision. All patients demonstrated some increase in capacity (15% to 70%),

and no patient in early follow-up clinically deteriorated and required enterocystoplasty.

Detrusorectomy, leaving a small cap of muscle at the dome through which a suprapubic tube can be placed, was proposed by Landa and Moorehead (1994). They were concerned that although these procedures usually improve compliance, increase in volume is “modest at best,” a concern shared by others (Snow and Cartwright, 1996; Cartwright and Snow, personal communication, 1998). In a report of 12 detrusorectomies, 5 patients were considered to have excellent results and 2 to have acceptable results, and 1 was lost to follow-up. Failures occurred in 4 patients, of whom 3 underwent conventional augmentation (Landa and Moorehead, 1994). In a combined series at those two institutions, only 52% of patients had a good result with autoaugmentation, whereas 20% had a poor outcome (Snow and Cartwright, 1996). Reoperative enterocystoplasty was not hampered by the prior detrusorectomy. The urothelial diverticulum at the time of augmentation cystoplasty was noted to be thick and fibrous, similar to a leather bag.

In general, complications from the procedures are uncommon. Perforation, a major concern after intestinal cystoplasty, has not been reported. Inadvertent opening of the mucosa during the procedure can make subsequent mobilization more difficult and may promote prolonged postoperative extravasation. Such extravasation usually stops with bladder drainage (Landa and Moorehead, 1994; Stothers et al, 1994). Prolonged drainage, however, may result in compromised results owing to collapse of the diverticulum. Rocha and coworkers (2011) suggested that early use of a silicone balloon to maintain distention may improve results. If concomitant ureteral reimplantation or bladder neck surgery is necessary, various authors have recommended that it be done first and the bladder then closed before detrusorectomy (Stothers et al, 1994).

Ehrlich and Gershman (1993) first reported laparoscopic myotomy (incision). A laparoscopic approach uses a smaller incision and perhaps shortens postoperative hospitalization; it may allow effective fixation of the detrusor muscle in an open fashion to make good bulging more difficult.

Concerns. The main disadvantage of autoaugmentation is a limited increase in bladder capacity such that adequate preoperative volume may be the most important predictor of success (Landa and Moorehead, 1994). If the maximum capacity and the

Figure 145-16. Autoaugmentation. A, The detrusor is incised. B, Detrusor is stripped and excised from mucosa. C, The detrusor muscle is anchored bilaterally so that the mucosa bulges with bladder filling. (From Cartwright PC, Snow BW. Bladder autoaugmentation: early clinical experience. *J Urol* 1989;142:505.)

volume of urine held at 40 cm H₂O are similar, the patient may be better served by immediate intestinal cystoplasty. It is of note that some patients have demonstrated clinical improvement after these procedures without a significant change in urodynamics. The reason for improvement in that setting is unknown.

In most series of autoaugmentation, no matter what the technique, occasional patients have been noted or concern has existed at the time of the initial procedure that adequate expansion was not achieved. In most such cases it was elected to proceed with enterocystoplasty immediately at the time (Landa and Moorehead, 1994). The patient and surgeon must be prepared for such an event on occasion. Stoehrer's group (1999) as well as Leng and associates (1999) reported good results with the technique among patients with hyperreflexia. In terms of capacity, even if adequate expansion is achieved initially, there is concern that any improvement may not persist long term (Dewan et al, 1994). In animals, the surface area of the autoaugmentation site was noted to decrease approximately 50% by 12 weeks. Progressive thickening and contracture of the site have been noted because of collagenous infiltrate (Johnson et al, 1994). Milam (personal communication, 2000) noted that almost one half of his adult patients with hyperreflexia who had a good early result after autoaugmentation failed with longer follow-up. Similar delayed failures have been noted in pediatric patients (Lindley et al, 2003) including one series with very poor results (MacNeily et al, 2003). To the contrary, Hansen and associates (2013) found that early decreases in capacity improvement may reverse with longer follow-up.

At this point, autoaugmentation should likely be considered only in patients who have reasonable capacity but poor compliance owing to uninhibited contractions. If a significant increase in capacity is needed, autoaugmentation may not be definitive.

Seromuscular Enterocystoplasty

Based on concerns about collagen deposition and contraction around autoaugmentation, efforts have been made to cover the bulging urothelium with demucosalized enteric segments. Use of bowel segments stripped of their mucosa within the bladder is not new. If exposed submucosa was left facing the bladder lumen, re-epithelialization with urothelium was noted in animals. Despite re-epithelialization, patch contracture often occurred (Oesch, 1988; Salle et al, 1990). Several series evaluated demucosalized augmentation in humans, with care taken to preserve the submucosa. Some encouraging results were noted (Lima et al, 1998; Dayanc et al, 1999; de Badiola et al, 1999; Lima et al, 2004), although regrowth of metaplastic enteric mucosa was found in the second study. Early placement of a silicone balloon or mold may help prevent contracture (Lima et al, 2004).

Technique and Results. To avoid contracture, a combination of autoaugmentation after detrusorectomy and coverage with a demucosalized enteric segment has now been used. Buson and colleagues (1994) used reconfigured, demucosalized sigmoid colon placed over the urothelium (seromuscular colocolocystoplasty lined with urothelium [SCLU]). They, and others, noted that the intestinal submucosa should be preserved to avoid contracture (Buson et al, 1994; Vates et al, 1997) (Fig. 145-17). This procedure has been performed clinically with early reports of good results in most patients (Gonzalez et al, 1994). Postoperative bladder capacity increased an average of 2.4-fold (139 to 335 mL) in 14 of 16 patients, and end filling pressure decreased from an average of 51.6 to 27.7 cm H₂O. In 2 patients the procedure failed, ileocystoplasty was required; their urodynamic data were excluded. Two other patients developed an hourglass deformity (Gonzalez et al, 1994).

Figure 145-17. Seromuscular enterocystoplasty with use of sigmoid colon. Detrusor incision is performed as in autoaugmentation; however, the bulging mucosa is covered with a demucosalized segment of sigmoid colon. (From Buson H, Manivel JC, Dayanc M, et al. Seromuscular colocolocystoplasty lined with urothelium: experimental study. *Urology* 1994;44:745.)

Endoscopic biopsy of the segments has been interesting. Of 10 biopsy specimens, 1 was noted to contain urothelium with islands of colonic mucosa, whereas 2 others were found to contain only colonic mucosa. Removal of all of the enteric mucosa is important when using sigmoid to prevent mucoceles or overgrowth of intestinal mucosa (Gonzalez et al, 1994; Lutz and Frey, 1994). Dewan and associates (1997) felt preservation of the submucosa eventually promoted regrowth of bowel mucosa. The interaction of the two different tissues will be interesting to follow. The long-term effects on the urothelium by the seromuscular segment and vice versa are unknown. Work has shown that persistent transitional lining will protect from metabolic problems and mucus production (Denes et al, 1997).

Dewan and Byard (1993) and Close and colleagues (2004) alternatively used demucosalized stomach to cover an autoaugmentation, first in sheep and then in patients. Early results showed improved bladder function both clinically and by urodynamics (Horowitz and Mitchell, 1993; Dewan and Stefanek, 1994; Horowitz et al, 1994; Robinson et al, 1994), although long-term results are not as encouraging (Carr et al, 1999). These procedures are technically more demanding than simple augmentation or autoaugmentation and are associated with more blood loss and a longer operative time (Gonzalez et al, 1994; Horowitz et al, 1994). Increased bleeding is particularly true when stomach is used. These urothelial-lined, seromuscular augmentations are theoretically attractive. Thus far, the failure and reoperation rate after such procedures remains higher than that noted for standard enterocystoplasty (Vates et al, 1997; Carr et al, 1999; Shekarriz et al, 2000; Jung et al, 2012). The best results have been reported with use of colon (Shekarriz et al, 2000; Jung et al, 2012). Early results may be partially attributed to the learning curve with a new, complex procedure. Longer follow-up and more experience are necessary to

determine whether the complication rate will decrease with experience or increase because of problems with the combination.

Bladder Regeneration

Efforts to find alternatives to intestinal cystoplasty in the 1950s included the use of alloplastic materials for bladder substitution (Gleeson and Griffith, 1992; Kropp et al, 1995b, 2004; Kanematsu et al, 2007; Lewis and Cheng, 2007; Yamzon et al, 2008; Roth et al, 2011). Early research efforts met with very limited success owing to foreign body complications but provided a foundation for regenerative medicine. This led to focus on biodegradable, collagen-rich tissues serving as scaffold with and without cell "seeding" for bladder regeneration (Kelami, 1971; Fishman et al, 1987; Atala et al, 1992; Kambic et al, 1992; Kropp et al, 1995a; Zhang et al, 2004; Harrington et al, 2008). Atala and coworkers (2006) provided the first reported data regarding use of a seeded biodegradable construct for augmentation in the neurogenic population. This work led to an industry-supported prospective multi-institution investigation using a neobladder construct (Joseph et al, 2009). Unfortunately, compliance improved in only four patients after 12 months and in five at 36 months, but in none to a clinically or statistically significant degree. Capacity did not improve either (Joseph et al, 2014).

Using autologous tissue from a neuropathic source may result in lower yield of cells for use (Subramaniam et al, 2011) or could potentiate growth of abnormal tissue; an alternate cell source for regenerative tissue such as stem cells might circumvent those concerns. The use of stem cells carries its own set of obstacles (Aboushwareb and Atala, 2008; Aitken and Bāgli, 2009; Soler et al, 2009; Chen et al, 2011). Further investigation into the clinical applicability of regenerative tissue engineering is required, but this technology remains poised to alter the field of reconstructive bladder surgery.

KEY POINTS: ALTERNATIVES TO GASTROINTESTINAL CYSTOPLASTY

- Ureterocystoplasty avoids complications associated with bowel segments but may not provide adequate volume if the ureter is not remarkably dilated.
- Autoaugmentation seldom adds significant capacity and may not always improve compliance long term.

CONTINENT URINARY DIVERSION

The frequency with which continent urinary diversion is performed in children is dependent on one's definition of continent diversion. Tumors resulting in cystectomy among children are much less common than in adults. It is in that setting, and the occasional child in whom the bladder is congenitally absent or so small as to be virtually useless, that a pure continent urinary diversion in the classic sense of an Indiana or Kock pouch might be performed. Very good results with continent diversion in children have been achieved, equivalent to those reported in adults (Stein et al, 2005). Orthotopic neobladders in children are performed very infrequently because neurogenic or anatomic problems at the outlet prevent spontaneous voiding in many cases. Occasionally a child with neurogenic dysfunction may be a candidate for orthotopic bladder substitution (Stein et al, 2000, 2005), but it is not clear how many of those patients with neurogenic dysfunction can be expected to void adequately.

Some authors have defined combinations of bladder augmentation, continent abdominal wall stoma, and some procedure at the outlet as continent diversions (Kaefer et al, 1997b). Division and closure of the bladder neck to prevent incontinence per native urethra has typically meant inclusion. These procedures typically have been performed in complex patients with multiple problems that must be addressed, often after numerous previous surgeries.

Considerations

The amount of bowel used in continent urinary diversion may vary depending on the patient. Total bladder replacement requires much more intestine than simple augmentation. Typically a 40-cm segment of small bowel is used for an ileal reservoir in a Kock pouch compared with the 20 cm often used for augmentation. Likewise, the entire right colon with the hepatic flexure may be used in an Indiana pouch, whereas only 15 to 20 cm of colon are needed for colocolostomy. Because of the potential morbidity associated with use of a larger intestinal segment, the native bladder is often used in children if it provides any significant volume. To do so, however, may require repair of the outlet if outflow resistance is low.

Imbrication of the ileocecal valve and terminal ileum has proven to be a simple and reliable means for construction of an effective efferent limb in continent diversion among adults and children. Despite reports to the contrary in select patients (Husmann and Cain, 1999), concern about fecal incontinence secondary to use of the ileocecal valve persists for patients with neurogenic dysfunction. The flap valve continence mechanism provides numerous alternatives for those surgeons with such concerns in continent diversion. Good results achieved with use of the appendix or tapered intestinal segments have led to their increased use.

Whereas maintenance of the native urethra for catheterization is ideal, it may not be appropriate or possible in all individuals. Urethras after reconstructive bladder neck procedures are often subject to difficulty with catheterization. Children with neurogenic sphincter incompetence may have associated neurologic limitations that prevent easy access to the native urethra. This is particularly true for the wheelchair-bound child. For children without neurologic deficits, normal sensation in the native urethra can prevent compliance with a routine catheterization

schedule because of discomfort. For these reasons, a continent catheterizable stoma provides an adequate and sometimes a more reliably useful alternative.

Continence Mechanisms and Catheterizable Stoma***Ureterosigmoidostomy and Its Variants***

Ureterosigmoidostomy can be an effective form of continent urinary diversion in some patients. Its advantage is the spontaneous evacuation of urine with stool. The significant complications of hyperchloremic acidosis, infection, hydronephrosis, and colonic malignancies have led to disfavor and disuse, particularly in the United States. Although good results with standard ureterosigmoidostomy have been reported in some children, the procedure is rarely performed as originally described. The morbidity of acidosis and upper tract changes may increase with time, making those complications particularly worrisome for children with a long life expectancy. The significant risk of adenocarcinoma commits the patients to a lifetime of close surveillance for an avoidable tumor. It is unlikely that ureterosigmoidostomy, as classically described, will regain acceptance for children.

Several modifications of ureterosigmoidostomy have been developed in an attempt to decrease the significant complication rate. The most basic of the modifications is the sigma rectum or the Mainz II pouch. The colon is incised along the antimesenteric border for 6 cm both proximal and distal to the rectosigmoid junction. The ureters are implanted in an antirefluxing fashion, and that portion of colon is then reconfigured and closed. This is done to create a rectosigmoid reservoir of lower pressure to protect the upper tracts. The Mainz II pouch has been used in children with bladder exstrophy (Stein et al, 1997a). Continence in appropriately selected patients is good, although acidosis is still a significant problem owing to exposure of the entire colon to urine (Fisch et al, 1996; Gerharz et al, 1999; Mingin et al, 1999b). The risk for development of adenocarcinoma is unaltered with this technique. Long-term follow-up is necessary to determine if the reconfiguration of the sigmoid in the area of ureteral implantation is truly effective for protection of the upper tracts. Stricture at the ureterocolonic anastomosis has been the most common complication in relatively short follow-up (Fisch et al, 1996).

In an effort to control the amount of colon to which urine is exposed, Kock and associates (1988) described creation of a colorectal valve to confine urine distally. The intussuscepted nipple valve was stabilized with permanent staples. The distal rectal segment was opened and patched with ileum to lower pressure. With short-term follow-up, the valve was effective in that no necessity for sodium bicarbonate or potassium citrate therapy was noted (Kock et al, 1988; Mahran et al, 1999). Urodynamic evaluation revealed low pressure in the rectal reservoir (Kock et al, 1988), but long-term follow-up in children is needed to see if it is truly less morbid in terms of infection and upper tract deterioration.

If placement of a colorectal valve avoids most complications of metabolic acidosis from ureterosigmoidostomy and creation of a reservoir with lower pressure better protects the upper tracts, the last remaining major concern about ureterosigmoidostomy is tumor development. The concern is significant; of 94 children followed in Boston after ureterosigmoidostomy, 7 developed adenocarcinoma, of whom 4 died of the tumor (Rink and Retik, 1991). Kock and colleagues (1988), followed by Skinner and associates (1989), used a hemi-Kock pouch to augment the distal rectal segment. A colorectal valve was created to isolate urine to the distal colonic reservoir. The afferent nipple valve kept stool away from the ureteroileal anastomoses, perhaps lowering the risk for tumor development. Simoneau and Skinner (1995) reported their results with the procedure in 15 patients, including 4 children. Their complication rate, both early and late, was relatively high. This is not surprising, considering the relatively complex nature of the procedure. They did think that pediatric patients were better suited for the procedure. Rink and Retik (1991) suggested that the rectum could be augmented with a nonrefluxing ileocecal conduit in a similar fashion.

Before any variant of ureterosigmoidostomy is considered, competence of the anal sphincter must be ensured. Tests used to assess sphincter integrity include manometry, electromyography, and practical evaluation of the ability to retain an oatmeal enema in the upright position for a period of time without soilage. Incontinence of a mixture of stool and urine results in foul soilage and must be avoided. Most patients with neurogenic dysfunction who are incapable of fecal continence in the presence of diarrhea are not candidates for these procedures. Procedures that separate the fecal and urinary streams within the rectal sphincter have been described but have not been widely used in children.

Nipple Valves

The most extensive experience with nipple valves used to achieve urinary continence has been with the Kock pouch. Skinner and associates (1989) made a series of modifications to aid in maintenance of the efferent nipple. Despite experience and use of these modifications, a failure rate of 15% or higher can be expected (Benson and Olsson, 1998) (Fig. 145-18). Several authors have reported a reoperative rate of approximately 33% with the Kock pouch, most frequently related to the efferent nipple (deKernion et al, 1985; Waters et al, 1987). Equivalent results with the nipple valve and a Kock pouch have been achieved in children (Hanna and Bloiso, 1987; Skinner et al, 1988; Kaefer et al, 1997b; Abd-El-Gawad et al, 1999). The last report noted a significant incidence of hyperchloremic acidosis and new hydronephrosis, although those complications were likely related to the complex nature of the patients rather than the particular continent diversion used.

Intussuscepted nipple valves have also been used with colonic and ileocolonic reservoirs, particularly the Mainz I pouch. Evolution of the nipple valve in the Mainz pouch also occurred over time (Thuroff et al, 1986; 1988; Hohenfellner et al, 1990; Stein et al, 1995). Most recently, the intussuscepted ileum was fixed with staples, passed through the intact ileocecal valve, and fixed again. Much as with the Kock pouch, the incidence of incontinence decreased with experience and modifications. The Mainz I pouch has been used in children with good results and low rates of incontinence using the latest modifications (Stein et al, 1995, 1997a; Steiner et al, 1998; Stein et al, 2000). Maintenance of normal upper tracts has been good, and metabolic problems rare (Stein et al, 1997b).

Flap Valves and the Mitrofanoff Principle

Mitrofanoff (1980) described a continence mechanism using the appendix and ureter to create a flap valve. He recognized that any

tubular structure could be implanted effectively into a low-pressure reservoir. This continence mechanism circumvents many of the secondary potential complications associated with harvesting the ileocecal valve or using other gastrointestinal segments.

The foundation for the success of the Mitrofanoff principle is based on creating a submucosal tunnel for a supple, small-diameter conduit. As the reservoir fills, the rise in intravesical pressure is transmitted through the epithelium and to the implanted conduit, coapting its lumen (Fig. 145-19). The appendix is an ideal tubular structure that can be safely removed from the gastrointestinal tract without significant morbidity. The small caliber of the appendix facilitates creation of a short functional tunnel within the bladder wall. Experience has shown that continence can be achieved with only a 2-cm appendiceal tunnel (Kaefer and Retik, 1997). Whether implanted into a bowel segment or native bladder, the appendix has been used as an efferent limb with very good results (Jayanthi et al, 1995; Kaefer et al, 1997b; Mollard et al, 1997; Cain et al, 1999; VanderBrink et al, 2011). The appendix has been particularly useful in children because it is relatively longer and the abdominal wall generally thinner. The flap valve is likely the most reliable of all of the surgically constructed continence mechanisms. Some patients with a flap valve virtually never leak per stoma; this potentially puts them at risk for upper tract deterioration or spontaneous rupture of the bladder or reservoir if catheterization is not routinely performed.

If the appendix is used in situ as a continence mechanism in a continent urinary reservoir, the reservoir by necessity will include the right colon. Duckett and Snyder (1986, 1987) used the right colon and appendix with good results in children. The mesoappendix, in most cases, allows mobilization of the appendix for use in the native bladder or virtually any reservoir.

Technique. In most children good exposure to the appendix and reservoir can be achieved through a low midline or a transverse incision. On occasion, the cecum may be high in the abdomen, and mobilization of the ascending colon along the line of Toldt may be required to gain access to the appendix and its mesentery. Cadeddu and Docimo (1999) have used laparoscopy to aid in the mobilization of the ascending colon and cecum. Once the cecum has been mobilized, the base of the appendix is amputated, leaving a small cuff of cecum with the appendix. Use of the cecal cuff at the stoma may decrease the risk of stenosis. The cecum is closed in a fashion similar to an open appendectomy. If the length of the appendix is marginal, a greater portion of the cecum can be harvested to effectively increase the functional length of the appendix (Cromie et al, 1991; Bruce and McRoberts, 1998).

After harvesting, a location is selected for implantation of the appendix into the bladder. The location is based on the length of

Figure 145-18. Continence mechanisms. A, The same pressures that create continence tend to efface nipple valves. B, This is not true of flap valves, which have been more reliable in pediatric reconstruction.

Figure 145-19. Appendicovesicostomy. A, The appendix is harvested with a cuff of cecum on a wide pedicle based on the appendiceal artery. A flap of cecum can be harvested in continuity with the appendix and tubularized to increase the length. B, The distal appendix is tunneled into the bladder to provide continence after the end is amputated. The proximal end of the appendix, the cecal cuff, is brought to the umbilicus or right lower quadrant as a catheterizable stoma.

the appendix, the mobility of the bladder, and the location for the appendiceal stoma. Typically the distal end of the appendix is tunneled into a posterolateral position within the bladder (see Fig. 145-19), although an anterior site may be useful as well. Creating a tunnel is easily done whether the bladder is opened or not (VanderBrink et al, 2011). Successful continence has also been achieved by developing an extravesical trough with or without a serosal base and then covering the channel with laterally mobilized serosa (Elshal et al, 2011; Baradaran et al, 2013).

The base of the appendix is brought to the abdominal wall in a location chosen preoperatively to suit the patient. It should be brought up to reach the skin without tension. Care must be taken not to twist the pedicle or occlude it as it passes through the abdominal wall fascia. The base of the appendix can often be hidden within the umbilicus, which allows for elimination of a small but obvious abdominal stoma. Because of the small circular diameter of the appendiceal base, stomal stenosis is common, and techniques have been described to prevent this problem. Various flaps have been described as a method for avoiding stomal stenosis (Keating et al, 1993; Kajbafzadeh, et al, 1995; Kaefer and Retik, 1997; Frane-Guimond et al, 2006; Berrettini et al, 2008; Landau et al, 2008). Weikert and associates (2012) described a rotational umbilical flap to enhance mobility and decrease tension when anastomosing to a channel with a short mesentery. Regardless of the technique, stomal stenosis remains the most common of complications. Chronic nighttime use of a stent through the channel may decrease that risk (Mickelson et al, 2009).

For prevention of kinking and problems with catheterization, it is advisable to maintain as short a conduit as possible. Securing the appendix and bladder wall to the peritoneum beneath the fascia will help diminish the problem of conduit kinking with reservoir filling. When appendix or any catheterizable stoma is used, it is advisable to repeatedly catheterize the channel after each step in reconstruction to confirm easy passage. If the catheter does not pass easily into the reservoir, the prior step needs to be revised. Problems with catheterization by the surgeon during the operative procedure usually result in more difficulty for the patient afterward. It is also beneficial to catheterize at variable reservoir volumes to confirm proper fixation of the reservoir and the absence of any kinking. The basic principles used for open reconstruction of a catheterizable channel can be used laparoscopically and with robotic assistance to achieve the same level of success (Hsu and

Shortliffe, 2004; Wille et al, 2011; Badawy et al, 2013; Famakinwa et al, 2013; Rey et al, 2013).

A 6-Fr to 12-Fr stent is typically left for 10 to 14 days within the efferent catheterizable channel during the healing process. It is then advisable for the surgeon to personally catheterize the efferent limb before the patient or family members do so. Catheterization should be repeated at least every 4 hours during the day for reservoir drainage, maintenance of patency, and minimalization of the risk of stomal stenosis.

The appendix may not be available for use in all patients owing to previous appendectomy, its location or length, congenital absence, involvement with adhesions, or its use for continence enemas. Histologic abnormalities of the appendix have been reported to occur in as many as 30% of patients (Liebovitch et al, 1992) and to increase with age. They rarely are of enough clinical significance to preclude use (Mulvihill et al, 1983).

Results. Several papers have reviewed large series of patients after appendicovesicostomy (Kaefer et al, 1997b; Cain et al, 1999; Harris et al, 2000; Thomas et al, 2006; Welk et al, 2008; VanderBrink et al, 2011). Inability to use the appendix, other than because it was needed for use in situ for antegrade continence enemas, has been rare. The results, in terms of continence, have been superb, usually above 95% (Kaefer and Retik, 1997; Mor et al, 1997; Suzer et al, 1997; Gerharz et al, 1998; Gosalbez et al, 1998; Cain et al, 1999; Castellan et al, 1999; Liard et al, 2001; Elshal et al, 2011; VanderBrink et al, 2011; Baradaran et al, 2012). Incontinence is a rare event with the Mitrofanoff principle and may result from inadequate length of the flap valve mechanism or persistently elevated reservoir pressure. Urodynamic evaluation is required to evaluate the cause of the incontinence. Injection of a bulking agent is a possible treatment for inadequate outflow resistance, with success reported up to 50% in the short term (Welk et al, 2008). A more formal approach with takedown and revision of the leaking Mitrofanoff valve is often required (Kaefer and Retik, 1997). The most common complication has been stomal stenosis, which in general has occurred in 6% to 10% of patients (Thomas et al, 2006; Welk et al, 2008; Leslie et al, 2011; Ardel et al, 2012). Stenosis resulting in difficult catheterization may occur early in the post-operative course and require formal revision (Harris et al, 2000). Mickelson and coworkers (2009) have described the successful use of an "L stent" with topical steroid cream as an effective noninvasive treatment. Another recognized complication has been appendiceal

perforation. Most problems with stomal stenosis and creation of a false passage (perforation) occur in the first few years after reconstruction, but long-term problems do occur, resulting in the need for lifelong monitoring (Thomas et al, 2006; Leslie et al, 2011). Benign fibroepithelial polyps and inflammatory granulomatous tissue have recently been reported in all types of catheterizable channels. Groth and associates (2013) reported an incidence of polyps occurring in 20% of their patients at a 7-year follow-up, with 50% being symptomatic and 45% having a recurrence after resection. Stricture and necrosis, particularly of cecal extensions of the appendix, have occurred rarely. Abdominal stomas may be associated with a higher risk of reservoir calculi owing to the potential for incomplete emptying.

Follow-up in the recent series has averaged approximately 4 years. Patients from Mitrofanoff's early experience (1980) now have follow-up of over 30 years, suggesting that the appendix may provide a durable alternative for pediatric patients, a finding also noted by others (Cain et al, 1999; Harris et al, 2000; Liard et al, 2001). Similar outcomes have been achieved in smaller series of adults (Gowda et al, 2008; Van der Aa et al, 2009; Ardel et al, 2012).

Alternatives. When the appendix is unavailable for use, other tubular structures can provide a similar mechanism for catheterization and continence. Mitrofanoff (1980) described a similar technique using ureter (Kaefer et al, 1997b). Care must be taken to preserve the distal blood supply to prevent ischemia. Refluxing ureters have even been used after extravesical reimplantation (Ashcraft and Dennis, 1986; Duel et al, 1996; Kaefer et al, 1997b). Stomal stenosis seems to be more problematic with use of the ureter compared with the appendix, possibly because of compromised blood supply. In addition, distention of the ureter from catheter passage has caused discomfort in some individuals (Duckett and Lofti, 1993).

Woodhouse and MacNeily (1994) used the fallopian tube, which can accommodate catheterization. Stenosis again appears to be a significant problem with the fallopian tube. The effect on fertility should be considered when there is a normal ipsilateral gonad. Ileum has been tapered to create a similar uniform tube of adequate length (Adams et al, 1992). By narrowing the ileal segment longitudinally along the mesenteric border using permanent staplers in series, a surrogate was constructed that was easy to catheterize and provided good continence. Others (Woodhouse and MacNeily, 1994; Hampel et al, 1995) have shown similar success with tapered ileum. The catheterizable channel must be long enough to reach from the reservoir to skin without tension, but kept as short and straight as possible to facilitate easy catheterization. An unnecessarily long, mobile catheterizable channel can kink and result in difficult catheterization or perforation.

Yang and Monti have been credited with a novel modification of the tapered intestinal segment that can be reimplanted according to the Mitrofanoff principle (Yang, 1993; Monti et al, 1997). A very short (1 to 2 cm) segment of small bowel is opened longitudinally along the antimesenteric border and then closed transversely (Fig. 145-20). By this reconfiguration, the initial circumference of the segment is converted to length and the original length to circumference. A very uniform tube is created with a small mesentery toward the center. The two ends are devoid of mesentery, making them very easy to tunnel into bladder and bring through the abdominal wall. If the first incision is made directly at the antimesenteric border, both limbs are of equal length. Because the incision is made off of midline and to one side, one limb may be created much longer than the other. Experience has shown that a long tunnel in the bladder or reservoir is not needed to achieve continence with such a small-diameter channel, and the longer limb has typically been used to reach the skin through a thick abdominal wall.

Very good results have been achieved using the Yang-Monti channel as a catheterizable stoma, and it is certainly an efficient use of bowel (Leslie et al, 2011; VanderBrink et al, 2011; Nerli et al, 2013). Some surgeons have suggested that it may be easier to catheterize than an ileal segment tapered longitudinally because circular mucosal folds are redirected longitudinally in the direction of

catheter passage. Stomas created with ileum may have a lower rate of stenosis than those created with appendix (Kaefer et al, 1999b). The one potential disadvantage of the Yang-Monti channel is that it remains relatively short and may not reach the skin without tension in obese patients. Despite extensive use of skin flaps, such tension may lead to stomal stenosis. Two separate reconfigured channels can be anastomosed together for increased length (Kaefer and Retik, 1997). Casale (1999) used an initial segment that was twice as long that was partially split in the middle and then opened in a spiral fashion on opposite sides to create a longer strip that could be tubularized in continuity. Narayanaswamy and associates (2001) noted difficulty with catheterizations through Yang-Monti channels in 28% of a large series of patients as a result of "pouch-like dilatation." Such a problem, to that degree, has been avoidable in most series. Excessive length of the limb may make such dilation more problematic.

Ileocecal Valve

Use of the ileocecal valve as a continence mechanism began with Gilchrist and colleagues (1950) and was popularized by the Indiana group (Rowland et al, 1985; Bihrlé, 1997). Various modifications have been developed. In general, a short segment of terminal ileum, whether imbricated or tailored, is used as an efferent limb. This segment should be kept as short and straight as possible to facilitate easy intermittent catheterization. Continence is based on the imbricated ileocecal valve, not the length of the efferent limb. The imbrication is usually secured with interrupted, permanent sutures, involving the very distal ileum and ileocecal valve, and the imbrication is carried onto the cecum.

The Indiana pouch has been used in children with excellent results as in adults. Besides the appendix, this continence mechanism is perhaps the simplest and has the shortest learning curve to achieve reliable results. Continence rates have been reported as high as 95% with preservation of normal upper tracts (Rowland et al, 1985; Lockhart et al, 1990; Rink and Bihrlé, 1990; Hensle and Ring, 1991; Rowland, 1995; Kaefer et al, 1997b). One report noted a higher rate of incontinence (Canning, 1998). Husmann and Cain (1999) have used the cecal segment for bladder augmentation and the efferent limb to construct a continent catheterizable stoma with good results. They noted a very low incidence of detrimental effect on gastrointestinal function in a select group of patients with neurogenic dysfunction.

Hydraulic Valves

Benckroun (Benckroun, 1982; Benckroun et al, 1989) developed a hydraulic valve as a continence mechanism that was modified by Guzman and colleagues (1989). Urine from the reservoir and generated pressure is allowed to enter a sleeve of ileum around the catheterizable channel. Compression of the inner tube theoretically provides continence, and early experience was encouraging. Initial continence rates approached 75% and then 90% with a single revision (Benckroun et al, 1989). Others have been unable to duplicate those results (Sanda et al, 1988; Leonard et al, 1990b). Koff and associates (1989) added a similar hydraulic sleeve around the efferent limb of an Indiana pouch, but the use of such valves has largely been abandoned.

Continent Vesicostomy

Yachia (1997) described creation of a bladder tube fashioned from a wide flap of the anterior bladder wall. An attempt to provide a continence mechanism was fashioned by weaving the bladder tube through the rectus muscle for compression and continence. Continence in their small, short-term series was reported to be 100%, but this has not been duplicated.

Hanna and associates (1999) described a continence mechanism based on either a flap of bladder or intestinal tissue fashioned after prior enterocystoplasty and used it on a very small series of patients. A rectangular flap in continuity with the bladder is tubularized over

Figure 145-20. Yang-Monti technique to efficiently construct a catheterizable tube. A, A 2-cm length of ileum is harvested either independently or next to a segment for augmentation cystoplasty. The segment is opened horizontally and tubularized in a longitudinal fashion. B, If the segment is opened directly on the antimesenteric border, two equal-length limbs result with a central mesenteric pedicle. Initial incision may be made to one side to form a shorter limb for implantation in the bladder and a longer one to be brought through the abdominal wall. C, The reconfigured ileal segment is tubularized over a 12-Fr catheter in a two-layer technique with absorbable sutures. D, A continent catheterizable stoma is constructed.

a 14-Fr to 16-Fr catheter. The bladder is plicated around the proximal 3 cm of the tube using nonabsorbable suture to create a type of nipple similar to gastric fundoplication. [Macedo and Srougi \(2000\)](#) described a similar continence mechanism created at the time of initial augmentation. They achieved acceptable continence in eight of their first nine patients. Their technique is potentially appealing for patients requiring augmentation and having no appendix because of the simplicity; however, continence is based on a type of nipple valve that historically has been difficult to keep fixed. The same forces that create continence tend to efface the continence mechanism.

[Casale \(1991\)](#) has described a form of continent vesicostomy in which the continence mechanism is based on a flap valve created from a tubularized strip of bladder mucosa. It is particularly

suitable when the bladder is compliant and of large capacity. An anterior detrusor strip is used to create a catheterizable limb.

Technique. Parallel incisions 3 cm apart are made into the anterior bladder and used to create a long rectangular flap. The abdominal wall should be measured to ensure that the strip is long enough to reach the skin without tension. The full-thickness strip is tubularized down to the bladder, in two layers. The muscle portion is left broad to come around without tension and provide good blood supply. The mucosa may be trimmed in width before tubularization to avoid redundancy. A strip of mucosa within the bladder, 2 to 3 cm in length and 1.5 cm in width, is incised in a direct line and in continuity with the mobilized bladder tube. The edges of this strip are mobilized until it can be tubularized along its entire length. It may be beneficial to mobilize only one edge over to the other side

to avoid overlapping suture lines. Casale (1991) originally incised the mucosa transversely at the end of the intravesical strip to be tubularized; Rink and colleagues (1995b) then suggested that it could be left intact (Fig. 145-21). The bladder mucosa from either side of the channel is then mobilized and closed over the mucosal

tube to create a flap valve. More extensive mobilization of the side opposite that mobilized for the inner tube allows closure without overlapping suture lines, which may help avoid fistula formation and incontinence. A stent is left in the channel for 3 weeks to prevent stenosis. It does tend to stricture if not catheterized

Figure 145-21. Casale continent catheterizable stoma. A, Parallel incisions are made in the bladder dome, forming a full-thickness bladder strip. B, The epithelium of the bladder is then incised for an additional 2.5 cm. The edges of the epithelium are mobilized, allowing tubularization. C, The epithelium is tubularized from the bladder out to the tip of the strip with an absorbable suture. The muscle of the bladder strip is then tubularized with an absorbable suture. D, The lateral edges of the epithelium within the bladder are reapproximated over the tubularized bladder segment with absorbable suture. The bladder is then closed with absorbable suture, incorporating the bladder tube with the initial sutures to prevent kinking.

regularly—more so than other catheterizable channels (Cain et al, 2002; Thomas et al, 2005).

Results. Continence rates have been good, as with most flap valves (Cain et al, 1999, 2002). Stomal stenosis remains a significant problem, 45% in the experience at Indiana University (Cain et al, 2002). Skin flaps and avoidance of tension to reach the skin may minimize this risk but not eliminate it. Advantages include avoidance of an intraperitoneal procedure and bowel anastomosis; the appendix can be reserved for use with enemas. It does use some bladder and decrease capacity, which may not be appropriate for many patients.

Results with Pediatric Continent Diversion

The most challenging aspect of continent diversion in children remains construction of an efferent limb that provides reliable continence and easy catheterization (Ardelt et al, 2012). The continence mechanism most familiar to pediatric urologists is the flap valve. The appendix is simple to use, suitable for most children, and associated with very good continence rates. If the appendix is not present or is to be used for antegrade colonic enemas, tapered intestinal segments provide a nice alternative. Nipple valves are the most complex continence mechanism and therefore have a longer learning curve. Continence rates approaching 85% can be expected with stapled nipple valves (Kaefer et al, 1997b; Benson and Olsson, 1998) after extensive experience. With use of the other efferent limbs, continence rates above 90% and approaching 95% have been reported in children (Duckett and Snyder, 1986; Hensle and Ring, 1991; Kaefer et al, 1997b; Surer et al, 2003; Ardelt et al, 2012).

Children undergoing continent diversion have a long life expectancy. With proper patient selection and appropriately performed continent diversion, postoperative hydronephrosis in children is rare and is not increased when compared with conduit diversion (Stein et al, 2000). If catheterization is not performed reliably, however, new hydronephrosis has been reported (Abd-El-Gawad et al, 1999). The incidence of complications after continent diversion will undoubtedly increase with longer follow-up. These patients will be subject to the same complications seen with bladder augmentation. All of those complications, including infection, hydronephrosis, calculi, spontaneous perforation, and tumor, have been reported after continent diversion in adults if not in children. These are largely a function of the use of intestine as a urinary reservoir. Because more intestine is usually required in continent diversion than bladder augmentation, the incidence of complications may ultimately be higher than with simple augmentation. Already, serum changes of increased chloride, decreased bicarbonate, and acidosis have been noted in some patients after continent diversion (Allen et al, 1985; Ashken, 1987; Thuroff et al, 1987; Boyd et al, 1989; McDougal, 1992a). Spontaneous perforation has occurred in up to 1.5% of patients (Mansson et al, 1997).

The most common complication in pediatric continent diversion, thus far, has been stomal stenosis. Stenosis occurs more commonly at the umbilicus with use of appendix compared with tapered ileal segments (Fichtner et al, 1997; Kaefer et al, 1999b). Various skin flaps may be placed into the terminal end of the appendix or intestinal segment to lower the rate of stenosis but do not eliminate it (Kajbafzadeh et al, 1995; Landau et al, 2008). Ardelt and associates, after extensive review (2012), found no consensus that a single type of efferent limb is superior and suggested that the choice of technique should be individualized according to the case.

SUMMARY

Every effort should be made to treat pediatric bladder dysfunction, no matter what the cause, early and aggressively to minimize the number of patients requiring reconstructive surgery for bladder and sphincter dysfunction. Some such surgery will still be necessary, and the patients must be carefully evaluated so that all problems are identified and addressed. The surgeon should then be flexible and prepared to use the bowel segments and techniques that best fit

KEY POINTS: CONTINENT URINARY DIVERSION

- “Pure” continent diversions have been used in children with good results similar to those expected in adults.
- Flap valves provide a reliable continence mechanism with appendix or reconfigured intestinal segments.
- The efferent limb should always be kept as short and straight as possible to facilitate catheterization.
- Stomal stenosis is the most common complication of pediatric continent diversion.

each patient. Although a given surgeon's results using any technique may improve with experience and confidence, each patient's unique problems and anatomy may make some choices better than others. Forcing one procedure to fit every patient should be avoided.

Preoperative evaluation should identify upper tract obstruction or vesicoureteral reflux. Such problems should be corrected at the time of surgery, although low-grade secondary reflux will usually resolve spontaneously with correction of bladder dysfunction. It is imperative to provide the patient with an adequate bladder or reservoir, one capable of holding at low pressure a urinary volume that will be produced between voidings or catheterizations. This can be accomplished by either augmentation or construction of a continent reservoir using any gastrointestinal segment. Each has its own set of advantages and disadvantages that should be considered. If adequate outflow resistance is lacking, it should be created at the bladder neck to prevent incontinence. Any patient undergoing reconstructive surgery for bladder or sphincter dysfunction must be prepared and capable of performing intermittent catheterization on a reliable basis; most will require it routinely. This is particularly true of those patients with neurogenic dysfunction.

As much of the patient's native urinary tract as possible should be preserved in pediatric urologic reconstruction. The urothelial lining avoids much of the morbidity associated with intestinal segments. If necessary, however, virtually any portion of the lower urinary tract may be reconstructed or replaced using intestine. Unfortunately, occasional complications do occur when intestinal segments are used in that manner. They are not perfect physiologic substitutes. Patients after reconstruction require a lifetime of follow-up, and that observation should include careful evaluation of their true quality of life. The most important factor in avoiding problems with such complex pediatric patients is the motivation of the patient and family to achieve a successful outcome. Assessment of that commitment is critical.

146 Management of Abnormalities of the External Genitalia in Boys

Lane S. Palmer, MD, FACS, FAAP, and Jeffrey S. Palmer, MD, FACS, FAAP

Normal Male External Genitalia	Hernia and Hydroceles
Penile Anomalies	Acute Scrotum
Scrotal Anomalies	Varicocele
Vascular Lesions of the Genitalia	Epididymal and Vasal Anomalies

The normal anatomy of the penis includes the prepuce (foreskin), glans, urethral meatus, coronal sulcus, and penile shaft. The ventral surface of the penile shaft has the median raphe contiguous with the scrotal raphe. Anomalies of the penis and scrotum are common and may be congenital, acquired, or iatrogenic. The congenital anomalies may result from a disorder of sexual differentiation, genital differentiation, or genital growth and may be associated with other syndromes (Table 146-1 on the Expert Consult website) or organ systems. For example, up to 50% of children with congenital anorectal malformations also have an associated urologic malformation.

Although ultrasonographic technology has evolved in the past decade, permitting earlier fetal sex determination (Efrat et al, 2006), it is inaccurate and is not recommended before 12 weeks of gestation (Odeh et al, 2009). However, ultrasonography after 13 weeks of gestation is accurate in sex determination in 99% to 100% of cases without malformed external genitalia (Odeh et al, 2009) (Fig. 146-1 on the Expert Consult website). In utero ultrasonography has identified abnormal male genitalia including ambiguous genitalia and penoscrotal transposition (Cheikhelard et al, 2000; Vijayaraghavan et al, 2002; Pinette et al, 2003). More recent ultrasonographic technology, including three-dimensional (3D) ultrasonography, is being used to evaluate the fetal external genitalia, but there are no definitive results suggesting this as an enhanced diagnostic modality (Verwoerd-Dikkeboom et al, 2008; Abu-Rustum and Chaaban, 2009).

The understanding of the normal anatomy and embryologic development of the male external genitalia is essential to recognizing and treating penile and scrotal anomalies. Most genital abnormalities noted in neonates do not result in an ambiguous appearance but rather more common conditions such as inconspicuous penis or abnormal penile orientation. The American Academy of Pediatrics (AAP) Committee on Genetics and Sections on Endocrinology and Urology (2000) published a guide to the normal embryology of the external genitalia and the altered embryology, evaluation, and management of ambiguous genitalia.

NORMAL MALE EXTERNAL GENITALIA

Embryology

Normal embryogenesis of the male genitalia involves the formation of the penis and scrotum. The early development of the external genitalia in the two sexes is similar before the 9th week of gestation (Ammini et al, 1997). Understanding factors and sequential steps in normal embryogenesis is fundamental in understanding the pathogenesis of male genital anomalies. These factors include testosterone synthesis by the fetal testis and its enzymatic conversion into dihydrotestosterone by 5 α -reductase and the presence of androgen receptors able to recognize the androgenic hormones. The influence of dihydrotestosterone on the androgen receptors results in the differentiation of the genital tubercle, genital (labioscrotal) folds, and genital swelling at 9 to 13 weeks of gestation into the male structures of the glans penis, penile shaft, and scrotum, respectively.

The male develops in a proximal-to-distal manner. As the penis forms from the elongation and enlargement of the phallus, the lateral walls of the urethral groove form from the ventrally located genital folds, which then fuse in the midline. The glanular urethra forms from the ingrowth of surface epithelium, but this long-held theory has been challenged with evidence suggesting that it is a result of the fusion of the urethral plate (Glenister, 1921; Ammini et al, 1997). The scrotum forms through the inferomedial migration and midline fusion of the genital folds as delineated by the scrotal raphe. In females and in males with abnormalities in testosterone and/or dihydrotestosterone production, 5 α -reductase deficiency, or androgen-receptor insufficiency, the genital tubercle, genital folds, and genital swellings passively become the clitoris, labia minora, and labia majora, respectively.

Penile Length and Tanner Classification

Penile length significantly increases with gestational age (6 mm at 16 weeks to 26.4 mm at 38 weeks) (Johnson and Maxwell, 2000;

TABLE 146-1 Male Genital Anomalies That Commonly Occur in Various Syndromes (Microphallus, Hypospadias, Ambiguous Genitalia, and Bifid Scrotum)

ANOMALY	FEATURES
Anencephaly Aniridia–Wilms tumor association	WAGR syndrome: Wilms tumor, aniridia, genitourinary abnormalities or gonadoblastoma, and mental retardation
Bladder exstrophy Börjeson–Forssman–Lehmann syndrome Carpenter syndrome CHARGE association	Microcephaly, mental retardation, large ears Acrocephaly, polydactyly and syndactyly of feet, congenital heart disease Coloboma, heart malformation, atresia choanae, retarded growth and development, genital anomalies, ear anomalies and/or deafness
Cloacal syndrome Fraser syndrome Johanson–Blizzard syndrome	Cryptophthalmos, mental retardation, ear anomalies Hypoplastic alae nasi, hypothyroidism, mental retardation, pancreatic insufficiency, deafness
Meckel–Gruber syndrome	Occipital encephalomeningocele, micrognathia, polydactyly, cystic renal dysplasia
Noonan syndrome Opitz syndrome Pallister–Hall syndrome Popliteal pterygium syndrome Prader–Willi syndrome Rapp–Hodgkin ectodermal dysplasia syndrome Rieger syndrome Robinow syndrome	Webbed neck, pectus excavatum, pulmonic stenosis, short stature Hypertelorism, hypospadias, mild-to-moderate mental retardation Hypothalamic hamartoblastoma, hypopituitarism, imperforate anus Popliteal web, cleft palate, lower lip pits Hypotonia, obesity, small hands and feet, mild to moderate mental retardation Hypohidrosis, oral clefts, dysplastic nails Iris dysplasia, hypodontia “Fetal face syndrome”; flat facial profile, hypertelorism, short forearms, thoracic hemivertebrae
Schinzel–Giedion syndrome	Growth deficiency, mental retardation, widely patent fontanelles, short forearms and legs, renal anomalies
Smith–Lemli–Opitz syndrome	Ptosis of eyelids, syndactyly of second and third toes, microcephaly, failure to thrive with short stature, mental retardation
Triploidy syndrome Trisomy 4p, 9p, 18, 20p, 21, 22, 9p, 10q, 11p, or 15q deficiency XXY, XXXXY

Figure 146-1. Fetal ultrasonogram of male genitalia. P, penis; S, scrotum.

Zalel et al, 2001) and during the first 3 months of life. The latter growth is a result of an increase in Leydig cell production of testosterone caused by the loss of the inhibitory effect of maternal estrogens on the fetal pituitary at birth, thereby causing a surge in gonadotropins. During the remainder of childhood, penile length increases more slowly until adolescence, when the length extensively increases again until the final size is reached. The normal penile size in a full-term male neonate is 3.5 ± 0.7 cm in the stretched length and 1.1 ± 0.2 cm in diameter compared with 13.3 ± 1.6 cm at adulthood. The penile stretched lengths from birth to adulthood are listed in Table 146-2. Sharony and colleagues demonstrated a positive correlation between prenatal penile length measurements and postnatal measurements (Sharony et al, 2012).

Tanner stages are a set of recognizable changes that occur to pubic hair, penis, and testes during puberty that are helpful in evaluating patients (Table 146-3). The stages range from preadolescent penis and testes with no pubic hair (stage 1) to adult-size penis and scrotum with adult pubic hair distribution (stage 5).

PENILE ANOMALIES

Prepuce (Foreskin)

Phimosis and Paraphimosis

At birth, a physiologic phimosis (Fig. 146-2A) with either partial or complete inability to retract the prepuce exists owing to natural adhesions between the glans and inner preputial skin and/or due to a preputial ring. Two factors are involved in the separation of the prepuce from the glans: (1) epithelial debris, referred to as smegma, accumulates under the prepuce during the first 3 to 4 years of age, and (2) intermittent penile erections. Preputial retractability increases with age, with 90% of uncircumcised boys 3 years of age

TABLE 146-2 Stretched Penile Length (cm) in Normal Male Subjects

AGE	MEAN \pm SD	MEAN $- 2.5$ SD
Neonate, 30-wk gestation	2.5 ± 0.4	1.5
Neonate, 34-wk gestation	3.0 ± 0.4	2.0

TABLE 146-3 Tanner Classification of Sexual Maturity Stages in Boys

STAGE	PUBIC HAIR	PENIS	TESTES
1	None	Preadolescent	Preadolescent
2	Scanty, long	Slight enlargement; slightly pigmented	Enlarged scrotum, pink, texture altered
3	Darker, starts to curl, small amount	Longer	Larger
4	Resembles adult type but less in quantity; coarse, curly	Larger; glans and breadth increase in size	Larger, scrotum dark
5	Adult distribution, spread to medial surface of thighs	Adult size	Adult size

Modified from Tanner JM. *Growth at adolescence*. 2nd ed. Oxford (UK): Blackwell Scientific Publications; 1962.

Figure 146-2. Conditions associated with the uncircumcised penis. A, Phimosis caused by a preputial ring. B, Paraphimosis with associated entrapped prepuce behind the glans penis.

with completely retractable prepuces and less than 1% by 17 years of age with phimosis (Oster, 1968; Kayaba et al, 1996). Thus, primary phimosis commonly resolves during childhood. Secondary phimosis may result from several causes, including forceful retraction and balanitis xerotica obliterans (BXO). Forceful preputial retraction should be discouraged to avert cicatrix formation.

Conditions associated with the uncircumcised penis include paraphimosis, infection, urinary tract infection (UTI), and cancer. Paraphimosis (Fig. 146-2B), the entrapment of the prepuce behind the glans penis, can result in gangrene if not reduced in a timely fashion by manipulation, dorsal slit procedure, or circumcision. Severe edema of the foreskin occurs within several hours, depending on the tightness of the tip of the foreskin, making reduction more difficult. In most cases, manual compression of the glans with placement of distal traction on the edematous foreskin allows reduction of the paraphimotic ring. Other treatments include application of an iced glove for 5 minutes, application of granulated sugar for 1 to 2 hours, and placement of multiple punctures in the edematous skin (Mackway-Jones and Teece, 2004).

Indications to enhance preputial retractability include persistent primary phimosis, secondary phimosis, balanitis, posthitis (i.e., inflammation of the prepuce), BXO, and UTIs. Several topical corticosteroid creams with different regimens have been successfully used to treat phimosis with a relatively small number of side effects. Palmer and Palmer (2008) compared the efficacy of two different topical betamethasone (0.05%) treatment regimens (twice daily for 30 days or three times daily for 21 days) and found an 84.5% and 87% response rate, respectively. Only one child had an untoward effect (candidal dermatitis).

Circumcision

Circumcision dates back more than 6000 years, with the oldest documented evidence thought to date to sixth dynasty (2345-2181 BCE) tomb artwork in Egypt. Since that time, different religions, countries, and cultures have adopted various views on circumcision (Palmer, 2009a). Many theories have been proposed regarding the origin of circumcision, including as a religious sacrifice, a rite of passage, an aid to hygiene, a way to differentiate cultural groups, and a method to discourage masturbation.

Elective circumcision in the neonate remains controversial. The AAP has historically weighed in on this subject. In 1989 the AAP concluded that neonatal circumcision offered potential medical benefits and advantages as well as disadvantages and risks, which should be explained to parents (AAP Task Force on Circumcision, 1989). In 1999, the AAP updated its policy statement (AAP Task Force on Circumcision, 1999; Lannon et al, 2000) emphasizing the importance of local anesthesia for the procedure. Most recently the AAP stated, "Although health benefits [significant reductions in the risk of UTI, risk of heterosexual acquisition of human immunodeficiency virus, and the transmission of other sexually transmitted infections] are not great enough to recommend routine circumcision for all male newborns, the benefits of circumcision are sufficient to justify access to this procedure for families choosing it and to warrant third-party payment for circumcision of male newborns" (AAP Task Force on Circumcision, 2012).

There are several techniques and devices for neonatal circumcision, including the Gomco clamp, Mogen clamp, and Plastibell device. There should be complete separation of the prepuce from the glans and complete inspection of the meatus and the corona to confirm the absence of anomalies, including hypospadias. When neonatal circumcision is performed, local anesthesia is recommended. Available options include the topical application of a cream containing eutectic mixture of local anesthetic (EMLA; lidocaine and prilocaine), a dorsal penile nerve block, and a penile ring block (Hardwick-Smith et al, 1998). Randomized controlled trials demonstrate the superiority of a dorsal penile nerve block to EMLA cream (Howard et al, 1999; Taddio et al, 2000), and prilocaine in the EMLA cream poses a low risk for methemoglobinemia (Couper, 2000). Typically, older infants and children are circumcised under general anesthesia, rather in the office, using freehand resection techniques.

Circumcision should not be performed in neonates with other penile conditions that require surgical correction. These conditions include hypospadias, penile curvature, dorsal hood deformity, buried penis, and webbed penis (see the corresponding sections). Other conditions commonly seen in neonates that should be taken into consideration are a large hydrocele or inguinal hernias, which are more likely to develop secondary phimosis, buried penis, and trapped penis. A patient with a coagulopathy is another contraindication.

Circumcision has several potential benefits, including the prevention of penile cancer, UTIs, sexually transmitted diseases including human immunodeficiency virus (HIV) infection, and phimosis, as well as lessening of the risk of balanitis. Although some have alleged that neonatal circumcision can lead to sexual dysfunction, this is not supported by long-term studies (Fink et al, 2002; Bleustein et al, 2005). Schoen and associates (2006) determined that neonatal circumcision has a cost benefit compared with postneonatal circumcision, including procedure charges and reduction in future health care costs.

Carcinoma of the penis develops almost exclusively in men who are not circumcised at birth. Phimosis is a significant risk factor (Tsen et al, 2001). Schoen and coworkers (2000b) reported that of 89 men in a large health maintenance organization with invasive penile cancer, only 2 (2%) had been circumcised at birth. Furthermore, of 116 men with penile carcinoma in situ, 16 (14%) had had a neonatal circumcision.

Uncircumcised neonates and infants are predisposed to UTIs (Singh-Grewal et al, 2005). In a study of 100 neonates with a UTI, Ginsburg and McCracken (1982) found that only 3 (5%) of the 62 boys who developed a UTI were circumcised. Subsequently, Wiswell and colleagues (1985) studied more than 2500 male infants and found that 41 had symptomatic UTIs; 88% of these infants were uncircumcised. Uncircumcised boys were almost 20 times more likely than circumcised neonates to develop a UTI. Other studies of larger groups of infants confirm these reports (Wiswell, 2000; Zorc et al, 2005) and demonstrate that neonatal circumcision is less costly than treating UTIs in uncircumcised boys (Schoen et al, 2000a). The increased risk seems to affect boys at least through 5 years of age (Craig et al, 1996), and the incidence of epididymitis is reduced (Bennett et al, 1998). The increased risk of UTIs can be attributed to colonization of the prepuce by urinary pathogens (Gunsar et al, 2004; Bonacorsi et al, 2005). It has been calculated that it takes 111 neonatal circumcisions to prevent one UTI (Singh-Grewal et al, 2005). However, Shim and colleagues (2009) evaluated 190 infants with confirmed normal urinary systems and diagnosed with their first febrile UTI for recurrent UTI during the following year. Thirty-four percent of infants with persistent nonretractile prepuces developed recurrent UTI, compared with 17.6% of infants with retractile prepuces.

Whether circumcision reduces the risk of sexually transmitted diseases has been controversial. Several recent reports of a large population of men have demonstrated reduced incidence of HIV infection among men, with a protective effect of 60% (Bailey et al, 2007; Gray et al, 2007). However, a recent study compared HIV transmission to HIV-uninfected female partners among 922 uncircumcised, HIV-infected, asymptomatic men, of whom 474 underwent immediate circumcision and 448 remained uncircumcised (Wawer et al, 2009). After 24 months of follow-up, 18% and 12% of women acquired HIV, respectively, concluding that circumcision of HIV-infected men did not reduce HIV transmission to female partners. It has been reported that circumcision may reduce the risk of ulceration, bacterial vaginosis, and trichomoniasis in female partners (Gray et al, 2009).

Several clinical trials of the effect of circumcision on the prevention of human papillomavirus (HPV) infection, herpes simplex virus type 2 (HSV-2) infection, and other sexually transmitted diseases (Auvert et al, 2009; Nielson et al, 2009; Tobian et al, 2009) have been done. Tobian and associates (2009) evaluated 5534 HIV-negative, uncircumcised males, with 3393 being HSV-2 seronegative at enrollment. Of the 3393 men, 1684 underwent immediate circumcision and 1709 were not circumcised, to evaluate HSV-2 and HPV transmission. At 24 months' follow-up, HSV-2 seroconversion was 7.8% and 10.3%, respectively, whereas prevalence of high-risk (carcinogenic) HPV genotypes was 18.0% and 27.9%, respectively.

This study underscores the benefit of circumcision in reducing the incidence of HSV-2 infection and the prevalence of HPV infection.

Circumcision Complications

The risk of complications after circumcision is 0.2% to 5% (Baskin et al, 1996; Christakis et al, 2000; Ben Chaim et al, 2005). Complications can occur immediately or months to years after a circumcision. The most common complication is bleeding, which occurs in 0.1% and is more common in older children. Bleeding is usually localized from the frenulum or, less frequently, from a large blood vessel on the penile shaft, or from a skin edge between the suture. The bleeding is usually self-limiting or may require compression. Occasionally cautery with an ophthalmic cautery or silver nitrate stick or a suture may be necessary. Wound infection is a rare complication, but antibiotic ointment (e.g., bacitracin) use after circumcision usually prevents its development. Penile degloving caused by excess skin removal or the edges of the penile skin not adhering to the mucosal collar can occur after circumcision. The penile shaft will usually epithelize, bridging the defect without any intervention other than the use of antibiotic ointment to the denuded region and warm baths to prevent eschar formation. Immediate suturing of the skin edges and skin grafting are not recommended to bridge the gap.

Penile Skin Complications. The amount of penile skin excised can also lead to complications after circumcision. Insufficient or asymmetrical prepuce excision can result in a cosmetic and social dilemma for the parents and child, especially as the child gets older (Fig. 146-3A). Unlike neonatal circumcision, circumcision revision requires general anesthesia. Several techniques have been described (Redman, 1995; Brisson et al, 2002; Ching and Palmer, 2008a). Excessive skin excision can result in penile chordee, torsion, and lateral deviation. These conditions, if necessary to repair, may require penile skin flaps or Z-plasty for closure. Excessive skin removal can also result in a trapped penis from a cicatricial scar. The trapped penis can be managed with betamethasone (Palmer et al, 2005), vertical relaxation incision, and formal repair. The use of 0.05% betamethasone in conjunction with manual retraction in children with a trapped penis resulting from a dense cicatrix of the residual foreskin distal to the glans has a 79% success rate in softening of the cicatrix with easy exposure of the glans or mild persistence of the cicatrix amenable to vertical relaxation incision (Palmer et al, 2005). Surgical correction includes excision of the cicatrix with possible need for penile skin flaps or Z-plasty for closure.

Glanular Adhesions and Skin Bridges. Glanular adhesions and skin bridges, attachments of the glans and penile shaft, are common complications associated with circumcision and are usually noticed

by the caregiver or primary medical provider. Both can occur in the well-circumcised penis and are usually the result of the physiologic retraction of the penis caused by a suprapubic fat pad and diaper irritation of the penis. Glanular adhesions are attachments between the inner prepuce or circumcision incision line attaching to the glans, with an incidence decreasing with age owing to epithelial separation of the adhesions (71% of infants, 28% of 1- to 5-year-olds, 8% of 1- to 9-year-olds, and 2% of children older than 9 years) (Van Howe, 1997; Ponsky et al, 2000). Persistent adhesions can be lysed in the office with the application of a topical analgesic such as EMLA cream or Pain Ease (Gebauer Company, Cleveland, OH) (1,1,1,3,3-pentafluoropropane and 1,1,1,2-tetrafluoroethane) (Palmer, 2009b). Use of low-dose corticosteroids has been relatively unsuccessful in lysing adhesions. Skin bridges (Fig. 146-3B) are epithelized adhesions that can lead to penile chordee and torsion, which can be excised in the office with the application of an analgesic (Palmer, 2009b) or in the operating room when the bridges are broad or thick and may require suturing of the glanular and shaft defects.

Meatal Stenosis. Meatal stenosis occurs in children almost only after circumcision during infancy (Fig. 146-4A). It can be congenital, occurring primarily in neonates with hypospadias, or acquired. The normal urethral meatus is 10 Fr before 4 years of age, 12 Fr from 4 to 10 years of age, and 14 Fr after 10 years of age (Litvak et al, 1976); this can be calibrated with a bougie à boule or sound. There are several proposed causes of secondary meatal stenosis. One theory is that after disruption of the normal adhesions between the prepuce and glans and removal of the foreskin, a significant inflammatory reaction occurs, resulting in a severe meatal inflammation and cicatrix formation. Other theories are frenular devascularization or chronic meatitis from diaper irritation of the exposed, unprotected meatus (Persad et al, 1995; Hensle, 1996). BXO is another cause of meatal stenosis (see later). A relatively small percentage of children will develop symptomatic meatal stenosis after neonatal circumcision. Symptoms include (1) typical urinary stream deviation in an upward direction resulting from a meatal baffle (Fig. 146-4B) or ventral web located at the inferior of the meatus, (2) a narrow, high-velocity stream, and (3) penile pain at the initiation of micturition. Urinary tract imaging usually does not reveal any obstructive changes in the urinary tract without other urologic issues but may be indicated for associated UTI or urinary incontinence. Meatotomy or meatoplasty to treat secondary meatal stenosis can be performed in the office with the use of topical lidocaine and prilocaine (EMLA) (Cartwright et al, 1996) or with general anesthesia by making a ventral incision long enough to create a normal meatal caliber. The suturing of the urethral mucosa to the glans with fine,

Figure 146-3. Complications associated with circumcision. A, Asymmetrical redundant penile skin. B, Penile skin bridge. C, Urethral and glanular resection.

Figure 146-4. Meatal complications associated with circumcision. A, Meatal stenosis. B, Meatal baffle.

Figure 146-5. Balanitis xerotica obliterans of the prepuce (A) and meatus (B). (Courtesy Warren Snodgrass, MD.)

rapidly absorbable sutures tends to reduce the risk of recurrence. An alternative but equally efficacious technique involves meatal tailoring using clamps without the need for suture (Cubillos et al, 2012). **Penile Trauma.** The most serious complications associated with circumcision are penile trauma, including urethral injury, excision of the glans and/or penile shaft, and penile necrosis (see Fig. 146-3C). Urethral injury requires urethroplasty, with the technique dependent on the severity of the excision. Excision of the glans can be repaired by suturing the excised tissue back to the penis, often without the need for microscopic repair (Sherman et al, 1996), yielding good results if performed within 8 hours. Penile necrosis can result from thermal injury from several causes, including cautery contacting the metal ring applied to the prepuce being excised or

the inappropriate use of lasers to perform a circumcision. Several options are available without ideal outcomes, including penile reconstruction and female gender reassignment with bilateral orchiectomy (Gearhart and Rock, 1989; Bradley et al, 1998). Although the cosmetic and functional results of phallic reconstruction have advanced, they are still being refined (De Castro et al, 2007; Monstrey et al, 2009). The issues with gender reassignment can include these children growing up with a male identity believed to result from in utero and neonatal androgen imprinting (Reiner, 1996; Diamond and Sigmundson, 1997; Diamond, 1999). **Balanitis Xerotica Obliterans.** Lichen sclerosus et atrophicus, or BXO, is a chronic infiltrative and cicatrizing skin condition resulting in pathologic phimosis (Chalmers et al, 1984) (Fig. 146-5).

BXO can affect the glans and meatus, as well as the urethra. The inability to retract the prepuce is the common presentation at puberty and is rare in children younger than 5 years of age (Oster, 1968). Other presenting symptoms include local infection, irritation, discomfort after micturition, bleeding, and occasionally acute urinary retention or urinary incontinence (Bale et al, 1987). Older patients and those with BXO involving the meatus may have a more severe clinical course (Gargollo et al, 2005). The cause of BXO remains unknown without an identified viral or bacterial cause or a familial predisposition. The association of BXO and penile cancer in children is also not established.

Treatment of BXO includes medical and surgical management. The use of topical corticosteroids has had limited benefit to treat mild BXO of the prepuce with minimal scar formation (Vincent and Mackinnon, 2005). Circumcision is the preferred treatment along with meatotomy or meatoplasty if there is meatal involvement. Children with meatal involvement should be observed postoperatively because of the risk of recurrent meatal stenosis. An approach that spares the prepuce was described by Wilkinson and colleagues on 104 uncircumcised boys for whom triradiate preputial incisions and injection of triamcinolone intralesionally were performed. This resulted in 81% having a fully retractile prepuce without macroscopic evidence of BXO; 13% developed recurrent symptoms or BXO requiring circumcision or repeat foreskin preputioplasty. The development of meatal stenosis occurred in significantly fewer boys than in those who underwent initial circumcision (Wilkinson et al, 2012).

Abnormal Penile Number

Aphallia

Penile agenesis results from failure of development of the genital tubercle (Roth et al, 1981) (Fig. 146-6). The disorder is rare, with an estimated incidence of 1 in 10 million to 30 million births. The karyotype almost always is 46,XY, and the usual appearance is that of a well-developed scrotum with descended testes and an absent penile shaft. The anus is usually displaced anteriorly. The urethra often opens at the anal verge adjacent to a small skin tag or may open into the rectum. The incidence of stillbirth or neonatal death is approximately one in three cases (Gilbert et al, 1990).

Associated malformations are common and include cryptorchidism, vesicoureteral reflux, horseshoe kidney, renal agenesis, imperforate anus, and musculoskeletal and cardiopulmonary abnormalities (Skoog and Belman, 1989; Evans et al, 1999). The

connection between the genitourinary and gastrointestinal tract is variable. Skoog and Belman (1989) reviewed 60 reports of aphallia and found that the more proximal the urethral meatus, the greater the likelihood of neonatal death and the incidence of other anomalies. Sixty percent of patients had a postsphincteric meatus located on a peculiar appendage at the anal verge; these patients had the highest survival rate (87%) and the lowest incidence of other anomalies (1.2 per patient). Twenty-eight percent of patients had pre-sphincteric urethral communications (prostatorectal fistula), and there was a 36% neonatal mortality rate. Twelve percent had urethral atresia and a vesicorectal fistula for drainage. This group had the highest incidence of other anomalies and a 100% mortality rate.

Children with this lesion should be evaluated immediately with a multidisciplinary approach. Testing should include a karyotype and other appropriate studies to detect associated malformations of the urinary tract or other organ systems. Magnetic resonance imaging (MRI) may be beneficial in determining the severity of the defect (Lapointe et al, 2001).

Consequently, the recommendation to perform gender reassignment should be made carefully and only after full evaluation by an ambiguous genitalia assessment team and parental counseling. Some of these patients have a male gender identity despite reconstruction as a female, presumably because of in utero or postnatal sex steroid imprinting (Reiner, 1996; Diamond and Sigmundson, 1997; Diamond, 1999). As a male, the patient would potentially be fertile; although current advances in phalloplasty and urethroplasty allow for sexual and voiding function (De Castro et al, 2013; Garaffa et al, 2014), reproductive function is unknown. Gender reassignment involves orchiectomy and feminizing genitoplasty in the neonatal period (Bruch et al, 1996; Gluer et al, 1998) and neovagina at a later age. Urinary tract reconstruction with simultaneous construction of an intestinal neovagina through a posterior sagittal and abdominal approach in patients with penile agenesis has been described (Hensle and Dean, 1992; Hendren, 1997).

Diphallia

Duplication of the penis is a rare anomaly with an incidence of 1 in 5 million live births (Hollowell et al, 1977) and has a range of appearances from a small accessory penis to complete duplication (Gyftopoulos et al, 2002). In some cases each phallus has only one corporal body and urethra, whereas others seem to be a variant of twinning, with each phallus having two corpora cavernosa and a urethra. The penises are usually unequal in size and situated

Figure 146-6. A, Neonate with aphallia. B, Urethral meatus at skin tag on anal verge.

Figure 146-7. Buried penis (A and C), which may be visualized by retraction of the skin lateral to the penile shaft (B and D).

adjacently. Other associated anomalies are common, including hypospadias, bifid scrotum, bladder duplication, renal agenesis or ectopia, and diastasis of the pubic symphysis (Maruyama et al, 1999). Anal and cardiac anomalies are also common. Evaluation should include imaging of the entire urinary tract, including a renal ultrasonogram and voiding cystourethrogram. Ultrasonography and MRI can also be done to assess penile development (Marti-Bonmati et al, 1989; Lapointe et al, 2001). The cause has not been delineated. Treatment must be individualized, with consideration of the associated anomalies with the goal of attaining a satisfactory functional and cosmetic result (Dean and Horton, 1991).

Inconspicuous Penis

An inconspicuous penis is one that appears to be small but with normal stretched penile length measured from the pubic symphysis to the tip of the glans (see Table 146-2) and normal diameter of the penile shaft (Bergeson et al, 1993). This condition can be congenital or acquired and is usually of great concern for parents. Several entities are included in this disorder, including buried penis, trapped penis, and webbed penis (Palmer and Kogan, 1995). These conditions must be differentiated from micropenis, in which the penis is abnormally small. When an infant has an inconspicuous penis, prompt evaluation is necessary for proper treatment and the family must be informed as to whether the penis is or is not normal.

Buried Penis

A buried penis, also referred to as a *hidden* or *concealed* penis, is a form of inconspicuous penis (Cromie et al, 1998). A buried penis

is a normally developed penis that is hidden away by the suprapubic fat pad. This condition can be classified into three categories based on cause of the concealment (Maizels et al, 1986; Casale et al, 1999): (1) poor penopubic fixation of the skin at the base of the penis, (2) obesity, and (3) a trapped penis from cicatricial scarring after penile surgery, typically a circumcision.

The congenital form of buried penis is believed to result from the inelasticity of the dartos fascia, which normally allows the penile skin to slide freely on the deep layers of the shaft, with restricted extension of the penis because the penile skin is not anchored to the deep fascia (Fig. 146-7). The acquired form from obesity typically seen in older children and adolescents is caused by abundant fat on the abdominal wall hiding the penile shaft. The other acquired form, a trapped penis, results from embedding of the penis in the suprapubic fat pad from scar formation over the glans. This deformity may occur after neonatal circumcision in an infant with significant scrotal swelling as a result of a hernia or hydrocele or after routine circumcision in an infant with a webbed penis. Also, in some neonates the penile shaft seems to retract naturally into the scrotum; and if circumcision is performed in this situation, the skin at the base of the penis may form a cicatrix over the retracted phallus. This condition should be differentiated from a transient buried penis resulting from a large suprapubic fat pad noted in early childhood that resolves with increased age and ambulation (Eroglu et al, 2009).

On examination, a buried penis must be differentiated from a micropenis with an abnormal penile stretched length. The clinician should determine whether the glans can be exposed by retracting the skin covering the glans (see Fig. 146-7). If so, it remains the surgeon's judgment whether correction is warranted.

B, Urine pooling caused by cicatricial scarring, increasing susceptibility to urinary tract infections. C, Penoscrotal web resulting in a webbed penis. D, Webbed penis with hypoplastic distal urethra.

However, if the penis is trapped by physiologic phimosis in the uncircumcised or cicatricial scarring (Fig. 146-8A) in the circumcised penis, this increases the chance of difficulty voiding, maintaining proper hygiene, balanitis, UTIs, and psychosocial issues (Fig. 146-8B) (Kon, 1983).

The treatment options for children with buried penis are based on the cause. Patients with buried penis secondary to obesity should have the underlying condition treated with referral back to the primary care provider for a weight loss and exercise program, which is essential; surgery may no longer be necessary. Young children with secondary cicatricial scarring after penile surgery can be managed with forceful dilation of the cicatrix with a fine hemostat in the office after the application or injection of analgesic. Another option is the combination of topical betamethasone and manual retraction (Palmer et al, 2005), which yielded complete resolution in the majority of boys or released the closing cicatrix, allowing for a simple incision of the phimotic ring; this reduced the need for formal surgical repair by 79%. If topical corticosteroid application is ineffective, correction under general anesthesia is necessary, with the usual recommendation of elective repair when the child is at least 6 months of age. The surgical technique is similar to that for the congenital buried penis.

A number of surgical techniques have been described to correct the buried penis (Maizels et al, 1986; Casale et al, 1999; Elder, 2001; Frenkl et al, 2004; Gillett et al, 2005; Borsellino et al, 2007; Karapetian and Palmer, 2007). The indications and timing for reconstructive surgery are controversial. In moderately severe cases the dysgenic bands of tissue, which are located primarily on the proximal dorsal surface of the shaft of the penis, must be removed. The prepuce should be unfurled and used for ventral skin coverage. In addition, the subcutaneous tissue on the dorsal aspect of the penis should be fixed to the pubic fascia, and then the subcutaneous tissue of the scrotum should be fixed to the ventral aspect of the base of the penile shaft. During correction one must be careful to avoid injury to the neurovascular bundles (Baskin, 1999; Baskin et al, 2000). Skin coverage can also be accomplished by penoscrotal Z-plasty, lateral penile shaft Z-plasty, island pedicle of ventral preputial skin, or a skin graft. Rarely, in the most severe cases the suspensory ligament of the penis must be divided, the suprapubic fat excised, and the spermatic cords protected. Liposuction has been reported to be helpful in severe cases (Maizels et al, 1986; Shenoy et al, 2000). However, this technique should be reserved for adolescent boys because prepubertal boys may lose their fat pad with somatic growth.

Webbed Penis

Webbed penis, also known as *penoscrotal fusion*, is a congenital or acquired condition resulting from the scrotal skin extending onto the ventrum of the penis. The congenital form of a penoscrotal web represents an abnormality of the attachment between the penis and the scrotum, whereas the penis, urethra, and remainder of the scrotum are normal (Fig. 146-8C). The acquired condition results from circumcision or other penile surgery, as a result of excessive removal of ventral penile skin.

Although the penoscrotal web is usually asymptomatic, the appearance is often unacceptable. There are several surgical techniques to correct this condition. Similar to the treatment of a buried penis, one technique involves the fixation of the subcutaneous tissue of the scrotum to the ventral aspect of the base of the penile shaft. On occasion, this condition may be corrected by incision of the web transversely, separation of the penis from the scrotum, and closure of the skin vertically. In other cases a circumferential incision is made 1.5 cm proximal to the coronal sulcus, a Byar preputial skin flap is transferred to the ventral surface of the penis, and the redundant foreskin is excised. In rare cases the distal urethra is hypoplastic, necessitating urethral reconstruction (Fig. 146-8D).

Micropenis

Micropenis is a normally formed penis that is at least 2.5 standard deviations (SD) below the mean size in stretched length for age (Aaronson, 1994) (Fig. 146-9). The ratio of the length of the penile shaft to its circumference is usually normal, but occasionally the corpora cavernosa are severely hypoplastic. The testes are usually small and frequently cryptorchid, whereas the scrotum is usually fused and often diminutive.

Stretched penile length correlates more closely with erectile length than does the relaxed penile length and should be compared with standards for penile length (see Table 146-2). Stretched penile length is determined by measuring the penis from its attachment to the pubic symphysis to the tip of the glans. The suprapubic fat pad must be depressed completely for an accurate measurement to be obtained, especially in an obese infant or child. In general, the penis of a full-term neonate should be at least 1.9 cm long. One must differentiate buried penis or webbed penis from the micropenis, with the former having a normal penile shaft.

Figure 146-9. Micropenis resulting from hypogonadotropic hypogonadism.

Micropenis results from a hormonal abnormality that occurs after 14 weeks of gestation. Differentiation of the male external genitalia is complete by the 12th week of gestation and requires a normal testis producing testosterone, stimulated by maternal human chorionic gonadotropin (hCG). During the second and third trimesters, growth of the penis occurs under the direction of fetal androgen, which is controlled by the secretion of fetal luteinizing hormone (LH). An abnormality in the production or use of testosterone results in a small penis and hypospadias, whereas a true micropenis often seems to be a consequence of a deficiency of gonadotropic hormones.

The causes of micropenis are many (Box 146-1 on the Expert Consult website) and include isolated gonadotropin defects and generalized endocrinopathies that may be associated with central nervous system defects. The most common causes of micropenis are hypogonadotropic hypogonadism, hypergonadotropic hypogonadism (primary testicular failure), and idiopathic (Lee et al, 1980b). Micropenis is often associated with major chromosomal defects, including Klinefelter syndrome (47,XXY) and other X polysomy syndromes, deletions, translocations, and trisomy involving chromosomes 8, 13, and 18 (Aaronson, 1994).

The most common cause of micropenis is hypogonadotropic hypogonadism, that is, failure of the hypothalamus to produce adequate quantities of gonadotropin-releasing hormone (GnRH). This condition may result from hypothalamic dysfunction, which can occur in Prader-Willi syndrome, Kallmann syndrome (genital-olfactory dysplasia), Laurence-Moon-Biedl syndrome (Walsh et al, 1978; Danish et al, 1980), and the CHARGE association (Ragan et al, 1999). Other causes include an associated growth hormone deficiency or neonatal hypoglycemia secondary to congenital hypopituitarism, congenital pituitary aplasia, and midline brain defects, such as agenesis of the corpus callosum and occipital encephalocele.

Primary testicular failure hypergonadotropic hypogonadism is another cause of micropenis and may result from rudimentary testes syndrome or gonadal dysgenesis. It also occurs in Robinow syndrome (Lee et al, 1980b). The test most frequently used to identify this subgroup is the failure of serum testosterone concentration to rise appropriately after stimulation by hCG. However, in patients with Kallmann syndrome and cryptorchidism, the serum testosterone level may not increase after the administration of hCG. Rarely, a patient with partial androgen insensitivity syndrome has micropenis, but sexual ambiguity is more common. Micropenis may also result from improper timing or delayed onset of gonadotropin stimulation in the fetus (Lee et al, 1980a). These patients have an idiopathic form of micropenis and a normal hypothalamic-pituitary-testicular axis.

The initial evaluation of a child with micropenis should include a thorough medical history, physical examination, and a karyotype at birth. Accurate measurement of the penile length, palpation of the corporal bodies, and evaluation for cryptorchidism are important elements of the physical examination. Consultation with a pediatric endocrinologist assists in determining the cause of the micropenis (central or testicular), assessing for other abnormalities, and helping to determine penile growth potential. Testicular function is assessed by measuring serum testosterone levels before and after hCG stimulation. Primary testicular failure produces an absent response and elevated basal concentrations of LH and follicle-stimulating hormone (FSH). In some cases, a GnRH stimulation test is also performed. Anterior pituitary screening tests include serial measurements of serum glucose, sodium, and potassium; serum cortisol concentrations; and thyroid function tests. MRI of the head assesses the anatomic integrity of the hypothalamus, anterior pituitary gland, and midline structures of the midbrain.

Before extensive evaluation of the hypothalamic-pituitary-testicular axis, androgen therapy should be administered to determine the end-organ response. In general, intramuscular testosterone enanthate is given for 3 months. Although prolonged treatment might advance skeletal maturation, short courses of treatment do not affect height. Transdermal testosterone also has been

Modified from Bin-Abbas B, Conte FA, Grumbach MM, et al. Congenital hypogonadotropic hypogonadism and micropenis: effect of testosterone treatment on adult penile size—why sex reversal is not indicated. *J Pediatr* 1999;134:579.

used in these patients (Choi et al, 1993). If androgen treatment in a neonate successfully increases the penis so that its size falls within the normal range, the effects at puberty have not been clearly delineated. In a mouse model of hypogonadotropic hypogonadal micropenis, significant prepubertal exposure of the penis to androgens reduced the ultimate growth response to androgens (Husmann and Cain, 1994; McMahon et al, 1995). Bin-Abbas and coworkers (1999) described eight boys with micropenis treated with androgens both at birth and at puberty. The final penile stretched length averaged 10.3 cm and was in the normal range in all cases. Therefore, exogenous stimulation at birth and at puberty with testosterone enanthate seems most reasonable (Tietjen et al, 1998) and is recommended until longer-term studies are available.

If the penis does not respond to testosterone, gender reassignment is an option but is controversial. Previously, gender reassignment was recommended, but this position has come under criticism owing to the implication that biologic factors during the prenatal period may affect gender identity. One such factor is testosterone-induced male brain imprinting (Diamond and Sigmundson, 1997). The lack of long-term data regarding the risks and benefits of reassigning these patients to a female gender (Calikoglu, 1999; Diamond, 1999) has resulted in a conservative use of this treatment option. Husmann (2004) described 20 adult men born with micropenis who had a suboptimal response to testosterone therapy and were raised as males. At adulthood, 90% had a micropenis and all had a male gender identity; 5 were undergoing psychiatric counseling for fear of rejection, and 8 had not been sexually active.

Several studies demonstrate that although ultimate penile size may be below the normal range, men born with micropenis have male gender identity and most have satisfactory sexual function. Reilly and Woodhouse (1989) described 20 patients with a primary diagnosis of micropenis in infancy. Almost all had received androgen therapy during childhood, but as adults none had a penis within the normal range of size. All of the boys stood to void. Parents of patients in the prepubertal group considered their children to be normal boys with a satisfactory penile appearance but did express concern about penile size and future sexual function. All of the patients in the adult group had a strong male identity, and 9 of the 12 patients were sexually active. In a study of 22 men born with micropenis, Lee and Houk (2004) had similar findings. Wisniewski and Migeon (2002) reported that their patients had a male gender identity but in general were dissatisfied with their genital appearance and function.

Abnormal Penile Orientation

Penile Curvature

Curvature of the penis may occur along the vertical (i.e., ventral or dorsal direction) or horizontal (i.e., lateral direction) plane of the penis. Penile curvature may be congenital or acquired after penile surgery (circumcision, hypospadias repair) or trauma and has consequences related to cosmesis and body image as well as future sexual difficulties. The indications for surgical repair include known associated sexual dysfunction, concurrent penile surgery, and surgeon's discretion regarding the likelihood of future sexual dysfunction with worsening curvature associated with penile growth.

Penile curvature is most commonly in the ventral direction, referred to as *chordee*, and is commonly associated with hypospadias. However, isolated chordee may occur with or without a dorsal hood of prepuce (Fig. 146-10) and is commonly associated with a deficiency of the ventral skin (Cendron and Melin, 1981). Ventral curvature in boys without hypospadias can usually be corrected by degloving of the penis, excision of fibrous tissue that is usually confined to the region superficial to Buck fascia, and development of Byar flaps for penile skin coverage, as necessary. In more severe cases, simple dorsal plication, Nesbit dorsal excision, or corporal rotation may be necessary. Urethral catheterization may be helpful in averting urethral injury during degloving. In the most severe cases the urethra is short and urethral reconstruction must be performed. Intraoperative artificial erection with injectable saline

Figure 146-10. Penile chordee and dorsal hood of foreskin without hypospadias.

confirms complete chordee correction. Some cases of chordee may be aggravated by a prominent frenulum, resulting in distal penile chordee with ventral glanular deflection. In these cases, the addition of frenulotomy will improve or correct the chordee.

Congenital dorsal penile curvature may be an isolated condition with or without asymmetrical penile skin or associated with epispadias and a ventral hood of prepuce. Some individuals may have hypospadias. Surgical repair of this condition without associated urethral anomalies is similar to chordee correction, involving degloving of the penis, excision of fibrous tissue that is usually confined to the region superficial to the Buck fascia, and development of skin flaps for penile skin coverage, as necessary. During correction, one must be careful to avoid injury to the neurovascular bundles (Baskin, 1999; Baskin et al, 2000). More severe cases involve plication and/or excision of ellipses from the ventral corporal bodies. Intraoperative artificial erection aids in determining the apex of the curvature and confirming chordee correction.

Lateral penile curvature is usually congenital and caused by overgrowth or hypoplasia of one corporal body. However, asymmetrical penile skin excision or postoperative scarring after circumcision or other penile surgery may also be a secondary cause. Lateral penile curvature may be unrecognized until later in childhood because the penis is normal when flaccid and only recognized as being curved when erect. Surgical repair of congenital lateral penile curvature involves degloving the penis and performing a plication and/or excision of ellipses from the corporal bodies from the area of maximum curvature to allow straightening of the penis. Secondary lateral penile curvature follows the same principles as for vertical curvature, with degloving of the penis, excision of fibrous tissue that is usually confined to the region superficial to the Buck fascia, and development of skin flaps for penile skin coverage as necessary. Intraoperative artificial erection may be necessary as described earlier.

Penile Torsion

Penile torsion is a rotational deformity of the penile shaft, usually in the counterclockwise direction (i.e., to the left side) (Fig. 146-11). In most cases, penile size is normal and the condition is unrecognized until circumcision is performed or until the foreskin is retracted. Penile torsion may also be associated with hypospadias, chordee, and other abnormalities involving the penile skin shaft, such as dorsal hood deformity without a urethral abnormality. In most cases the median raphe spirals obliquely around the shaft and inserts atypically rather than at the base of the glans in line with the urethral meatus. The cause of penile torsion has not been clearly delineated but may be the result of an anomalous arrangement of penile shaft skin.

Most forms of penile torsion are less than 60 degrees. If surgical repair is being considered, neonatal circumcision is discouraged

and then performed at the time of penile detorsion. Although the glans may be directed more than 90 degrees from the midline, the orientation of the corporal bodies and the corpus spongiosum at the base of the penis is normal. In mild forms of penile torsion, correction typically involves degloving the penile skin, rotating the glans in the direction opposite to the defect (i.e., clockwise rotation for a counterclockwise abnormality), and suturing the glans to the penile skin, resulting in a glans in a normal configuration (Bar-Yosef et al, 2007). In some instances the median raphe may take a serpentine course that prevents restoration to a normal position; this is not critical as long as the meatus has a normal configuration. However, in boys with penile torsion of 90 degrees or more, simple shaft skin rearrangement is insufficient. Instead, the base of the penis must be mobilized so that dysgenic bands of fibrous tissue can be identified and incised. If the penis still remains rotated, correction may be accomplished by placing nonabsorbable anchoring sutures at the base of the corpora cavernosa (Pomerantz et al, 1978;

Slawin et al, 1992; Elder, 2001). Other surgical techniques have been described, including the use of a dorsal dartos flap (Bauer and Kogan, 2009) and mobilization of the urethral plate and urethra (Bhat et al, 2009).

Penile Masses

Penile cysts, congenital or acquired, are the most common penile masses in children. A history of onset, previous surgery, and changes in appearance or size are important in the evaluation of these lesions.

Parameatal Urethral Cyst

The parameatal urethral cyst is a rare anomaly and appears as a small blister in proximity to the urethral meatus (Fig. 146-12A). Shiraki (1975) suggested that these cysts may result from occlusion of paraurethral ducts or in other cases from faulty preputial separation from the glans along the coronal sulcus. The cyst wall may consist of transitional and squamous or columnar epithelium. Treatment is complete excision of the cyst with the patient under anesthesia, with care taken not to cause meatal stenosis.

Inclusion Cysts

The most common acquired cystic lesion of the penis is entrapped smegma under the unretractable prepuce. The mass may appear yellow because of smegma. The prepuce usually does not need to be retracted because it almost always retracts on its own with time.

Epidermal inclusion cysts may form after penile surgery, including circumcision and hypospadias repair, owing to islands of epithelium within the subcutaneous tissue (Fig. 146-13). Excision of the epidermal inclusion is recommended.

Cyst of the Median Raphe

Congenital epidermal cysts tend to form along the median penile raphe on the glans or penile shaft, scrotum, or perineum (see Fig. 146-12B and C) (Little et al, 1992; Krauel et al, 2008). These congenital lesions may result from epithelial rests that become buried during the urethral infolding process or represent a mono-dermal teratoma. Rare cases of cysts enlarging and extending into the pelvis are reported (Huang et al, 1999). Excision with the use

Figure 146-14. Congenital penile nevus on the penile shaft.

of general anesthesia is recommended unless the cysts are small and asymptomatic.

Congenital Penile Nevi

Congenital penile nevi are pigmented lesions that can form on the glans and penile shaft (Fig. 146-14). Nevi can be classified based on the location of melanocytes: dermal (involving only the dermis), junctional (involving only the dermal-epidermal junction), and compound (involving the dermis and dermal-epidermal junction). They tend to be superficial and benign and should be excised (Papali et al, 2008).

Juvenile Xanthogranuloma

Juvenile xanthogranuloma is an uncommon benign, self-limiting lesion of the penis predominantly seen in infancy or early childhood. These lesions appear as solitary or multiple pigmented (yellow, orange, gold, brown, or red) nodules of rapid onset. They measure 2 to 20 mm in diameter and are well demarcated, firm, and rubbery. These lesions can affect the penis (Hautmann and Bachor, 1993; Bradford and Choudhary, 2009) or scrotum (Goulding and Traylor, 1983; Dehner, 2003), with as many as 20% being

present at birth. The lesion is often self-limited, and a period of 1 year of expectant monitoring is advised to avoid potentially unnecessary ablative genital surgery.

Accessory Urethral Openings

Congenital Urethral Fistula

Congenital urethral fistula is a condition whereby the urethra and meatus are normal and a urethrocutaneous fistula is present, typically located in the coronal or subcoronal position. This abnormality is usually an isolated deformity (Tennenbaum and Palmer, 1994), but may be associated with imperforate anus or ventral chordee (Ritchey et al, 1994). In a series of 14 such cases, 4 patients had distal hypospadias and 2 had chordee (Caldamone et al, 1999). The cause is unknown but may involve a focal defect in the urethral plate preventing the urethral folds from fusing. The diagnosis is made after circumcision in some cases (Caldamone et al, 1999), raising the possibility that the fistula is instead an iatrogenic injury. Surgical correction may require circumscription of the fistula and closure in multiple layers, similar to a urethrocutaneous fistula after hypospadias repair; or if the glans bridge is thin, the ventral glans can be opened through the distal urethra and then repaired by Thiersch-Duplay tubularization and incision of the urethral plate as needed.

Urethral Duplication

Urethral duplication is a rare congenital anomaly, with roughly 200 reported cases (Salle et al, 2000; Slavov et al, 2007). The duplication most commonly occurs in the sagittal plane with one urethra located ventrally and the other dorsally (Fig. 146-15). Collateral urethral duplication in which urethral duplication occurs in the same horizontal plane is extremely rare (Ching and Palmer, 2008b). In a series by Salle and colleagues (2000), sagittal plane duplication accounted for 94% of urethral duplication. Usually the dorsal urethra is considered the accessory urethra with or without a urinary stream, whereas the ventral urethra carries the urine stream and the anatomic landmarks such as the external sphincter and verumontanum. The most commonly used classification of urethral duplication is that of Effman (Fig. 146-16), which describes three types: types I and II distinguish between partial and complete urethral duplication; type III describes urethral duplication as part of bladder duplication (Effman et al, 1976). The embryology of urethral duplication is not well established, with explanations including ischemia (Woodhouse and Williams, 1979; Podesta et al,

Figure 146-15. Urethral duplication with catheters through meatus at tip of the glans penis and at perineum.

1998) and abnormal müllerian duct termination (Das and Brosman, 1977). Effman and coworkers (1976) suggested that caudal duplication may be related to division of the notochord with subsequent formation of two hindguts, allantoises, and cloacae.

Associated genitourinary, gastrointestinal, and musculoskeletal anomalies may be present. In the review by Podesta and colleagues (1998), six of seven patients with urethral duplication had other associated anomalies, with vesicoureteral reflux being the most common. Other anomalies included renal agenesis, bilateral cryptorchidism, sacral agenesis, imperforate anus, radial hypoplasia, and tracheoesophageal fistula. There appears to be an association with other midline defects such as duplicated bladder, duplicated colon, imperforate anus and anorectal agenesis, bifid glans, thoracic hemivertebrae, and partial sacral agenesis (Woodhouse and Williams, 1979; Fenster et al, 1980; Kennedy et al, 1988; Salle et al, 2000).

The most common presentation of urethral duplication is a double meatus and double urinary stream (Kennedy et al, 1988; Urakami et al, 1999; Salle et al, 2000). Incontinence and recurrent UTIs are other common presentations. Less common conditions include penile chordee and urinary obstruction secondary to a mucosal flap at the urethral bifurcation acting as an occluding valve during voiding (Effman et al, 1976; Das and Brosman, 1977; Salle et al, 2000). The presence of incontinence is dependent on the site of origin of the accessory urethra; the more proximal the site of urethral duplication, the higher the incidence and the greater the degree of incontinence (Farrell and Sparnon, 1987).

Patient evaluation should include a voiding cystourethrogram, retrograde urethrogram, and direct visualization of the anatomy during cystourethroscopy. Evaluation of the other associated anomalies should also be undertaken. Treatment of urethral duplication is usually reserved for the symptomatic child (Urakami et al, 1999). Cosmesis alone, however, has been advocated by some as a valid indication for intervention (Middleton and Melzer, 1992). The accessory urethra should not be used as the primary urethra secondary to being hypoplastic with the risk of inadequate urine flow (Salle et al, 2000). Surgical repair includes complete accessory tract excision, electrofulguration or injection of sclerosing agents into the accessory tract, septotomy if the septum between the two urethras is thin, and urethrourethrostomy of the accessory tract into the functional urethra. Management is dependent on the anatomy

Figure 146-16. Effman classification.

of the urethral duplication (Farrell and Sparnon, 1987; Podesta et al, 1998).

Genital Lymphedema

Lymphedema of the genitalia, congenital or acquired, is a disfiguring disorder characterized by impaired lymphatic drainage that causes progressive penile or scrotal swelling. Congenital lymphedema may be sporadic (85%) or inherited (15%) and can be expressed at various ages (McDougal, 2003). Milroy disease is an autosomal dominant inherited trait, whereas Meige disease is probably autosomal dominant with variable penetrance and occurs in the first or second decade (Wheeler et al, 1981). If the genital lymphedema occurs at puberty and is sporadic, it is termed *lymphedema praecox*. Approximately 80% of patients with congenital lymphedema demonstrate onset of the disease at puberty (McDougal, 2003). The lymphedema may involve the penis, the scrotum, or both. Congenital lymphedema has been associated with several syndromes, including Turner, Noonan, Klinefelter, and intestinal

lymphangiectasia syndromes. Lower extremity involvement may also occur.

Initial management involves observation, but surgical therapy is necessary if the lymphedema remains significant or progresses. The goal of surgical treatment is to remove all involved tissue. On the penile shaft, the penis is degloved and all tissue between the Buck fascia and the skin as well as redundant penile skin must be excised. If the patient is uncircumcised, the prepuce may be unfurled to provide coverage of the penile shaft (Shenoy et al, 2001). If the scrotum is involved, the scrotal skin must be excised, with the exception of the posterior skin, and the spermatic cords and testes should be preserved (Ross et al, 1998). The penis may be covered with local skin flaps, and the scrotal contents may be covered with uninvolved posterior skin flaps (Bolt et al, 1998; Ross et al, 1998). Split-thickness skin flaps may be needed to cover the penis and scrotum if inadequate healthy skin is available (McDougal, 2003). Parents should be counseled that lymphedema in adjacent areas may recur after definitive surgical therapy.

Priapism

Priapism, a prolonged penile erection sustained for longer than 4 hours with the absence of both physical and psychological stimulation, is commonly painful. Tumescence is usually restricted to the corpora cavernosa (Montague et al, 2003), and in some cases the corpus spongiosum involves the glans. Priapism can be categorized into three types:

1. Ischemic (veno-occlusive, low-flow) priapism is characterized by little or no cavernous blood flow, and cavernous blood gases are hypoxic, hypercapnic, and acidotic. The corpora are rigid and tender to palpation.
2. Nonischemic (arterial, high-flow) priapism is caused by unregulated cavernous arterial inflow. Typically, the penis is neither fully rigid nor painful. There is often a history of antecedent trauma resulting in a cavernous artery or corpora cavernosa fistula.
3. Stuttering (intermittent) priapism is a recurrent form of ischemic priapism with painful erections with intervening periods of detumescence.

Low-flow priapism is most commonly secondary to homozygous sickle cell disease, which is characterized by predominance of sickle hemoglobin (HbS). Other causes include leukemia, other hemoglobinopathies, and local malignancy (Dewan et al, 1989; Friedman, 1998). Sickle cell–induced priapism occurs in 2% to 29% of males with the disease (Tarry et al, 1987; Hamre et al, 1991; Miller et al, 1995; Mantadakis et al, 1999). The priapism associated with sickle cell disease is generally related to sickling of red blood cells within the sinusoids of the corpora cavernosa during normal erection, resulting in venous stasis. The resulting decreased pH and local oxygen tension potentiates further stasis and sickling (Bruno et al, 2001). Priapism typically occurs during sleep, when mild hypoventilatory acidosis depresses oxygen tension and pH in the corpora or as a result of oxyhemoglobin desaturation (Roizenblatt et al, 2012). The pain that is experienced is a sign of ischemia.

Transient prolonged erections lasting less than 2 hours, stuttering priapism, is more common than prolonged erections in the patient with sickle cell disease. Pseudoephedrine, an oral α -adrenergic agent, given at bedtime promotes muscle contraction within the erectile tissue. If this treatment is unsuccessful, other agents can be used, including an oral β agonist. Recently, preliminary findings have suggested that the use of continuous, long-term oral phosphodiesterase type 5 (PDE5) inhibitor therapy may prevent recurrent priapism based on the hypothesis that PDE5 dysregulation may be involved in priapism (Burnett et al, 2006; Burnett, 2008).

The initial treatment of low-flow priapism resulting from sickle cell disease is conservative, with hydration, oxygenation, alkalinization, analgesia, and exchange transfusion aimed at reducing HbS concentration (Seeler, 1973; Hamre et al, 1991; Miller et al, 1995). Evacuation of blood and irrigation of the corpora cavernosa along with intracavernous injections of α -adrenergic

sympathomimetic agents, such as phenylephrine or epinephrine solution, can be a concurrent therapy (Montague et al, 2003). Surgical shunt procedures to facilitate corporal drainage are indicated in the absence of response to medical therapy (Tarry et al, 1987; Miller et al, 1995; Chakrabarty et al, 1996). Surgical shunting bypasses the veno-occlusive mechanism of the corpora cavernosa and thereby enhances blood drainage. Shunt procedures include distal cavernoglanular shunt (Winter, Ebbehøj, and Al-Ghorab shunts) (Ebbehøj, 1974; Winter, 1976; Ercole et al, 1981), proximal cavernospongiosal shunt (Quackels and Sacher shunts) (Quackels, 1964; Sacher et al, 1972), or saphenous vein anastomosis to one of the corpora cavernosa (Grayhack shunt) (Grayhack et al, 1964). Parents should be educated on the potential side effects from intervention, including cavernosal fibrosis and erectile dysfunction.

High-flow priapism is usually a result of perineal trauma, such as a straddle injury. Other causes include Fabry disease and sickle cell anemia (Ramos et al, 1995; Callewaert et al, 1998; Volkmer et al, 2001). Corporal irrigation is diagnostic and therapeutic. Typically, the aspirated blood is bright red and the aspirate is similar to arterial blood on blood gas analysis. Color Doppler ultrasonography (CDUS) often will demonstrate the fistula. The initial management is observation (Montague et al, 2003) because spontaneous resolution may occur. Superselective embolization of cavernous and penile arteries (Callewaert et al, 1998; Volkmer et al, 2001; Montague et al, 2003; Kuefer et al, 2005) is the next line of therapy.

A fourth type of priapism is a spontaneously resolving form observed in neonates (Walker and Casale, 1997). Causes may include idiopathic factors, birth trauma, and polycythemia. No intervention is necessary because the priapism usually resolves in 2 to 6 days without adverse results.

Penoscrotal Transposition (Scrotal Engulfment)

Penoscrotal transposition may be partial or complete (Fig. 146-17), with its less severe forms having been termed *bifid scrotum*, *doughnut scrotum*, *prepenile scrotum*, and *shawl scrotum*. The embryologic cause may result from incomplete or failed inferomedial migration of the labioscrotal swellings. The use of 2D and 3D ultrasound during gestation has been successful in identifying the condition in utero (Wang et al, 2011). Frequently, it occurs in conjunction with perineal, scrotal, or penoscrotal hypospadias with chordee (Pinke et al, 2001). Penoscrotal transposition has also been associated with caudal regression (Lage et al, 1987), sex chromosome abnormalities (Yamaguchi et al, 1989), and Aarskog syndrome (Shinkawa et al, 1983). As many as 75% of patients with complete penoscrotal transposition and a normal scrotum have a significant urinary tract abnormality, including renal agenesis and dysplasia (MacKenzie et al, 1994; Parida et al, 1995), and other nongenitourinary anomalies have been reported. These patients

Figure 146-17. Penoscrotal transposition.

should be evaluated with renal ultrasonography and voiding cystourethrography.

Surgical repair is usually performed during hypospadias or other penile repair. Several scrotoplasty techniques have been described (Glenn and Anderson, 1973; Ehrlich and Scardino, 1982; Levy et al, 1997) with the goal of freeing the penis from the scrotum, developing skin flaps, relocating the scrotum to a dependent position, and moving the penis superiorly. When scrotal engulfment is associated with severe hypospadias, hypospadias repair is often accomplished by a transverse preputial island flap in conjunction with Thiersch-Duplay tubularization of the proximal urethra. To minimize the possibility of devascularization of the preputial flap, correction of the scrotal engulfment is usually done as a second-stage procedure 6 months later (Elder and Duckett, 1990; Germiyanoglu et al, 1994). If the penis is normal, scrotoplasty can be accomplished when the child is 6 to 12 months of age.

Scrotoplasty is performed by circumscribing the superior aspects of each half of the vertical aspect of the scrotum and extending these incisions laterally to include at least half of the scrotum (Fig. 146-18). The medial aspects of the incision are joined on the ventral aspect of the penis, and the incision is carried down the midline along the median raphe. The injection of a solution of lidocaine with epinephrine into the subcutaneous tissue can be used to develop tissue planes and also help to diminish bleeding. Care must be taken not to injure the tunica vaginalis and spermatic cord during deeper dissection. The scrotal wings are rotated medially under the penis and sutured together in the midline in an everted manner. Although in most cases there is no deficiency of the ventral penile shaft skin, in more severe cases of penoscrotal transposition dorsal interposition flaps may be necessary, allowing caudal advancement of the skin of the abdominal wall (Pinke et al, 2001).

An alternative technique is to identify the correct position for the penis and make a buttonhole by excising a plug of epidermis, dermis, and suprapubic fat (Kolligian et al, 2000). The penis is then degloved, and the penile shaft is brought through the buttonhole. The penile shaft skin remains behind, is split down the ventrum, and is mobilized superiorly to the penile shaft. A window of the dartos pedicle is made, and the penile shaft is brought through this window. The degloved penis is then resurfaced with shaft skin.

Figure 146-18. Repair of penoscrotal transposition (see discussion in text).

SCROTAL ANOMALIES

Bifid Scrotum

Bifid scrotum refers to the deformity in which the labioscrotal folds are completely separated and without a median raphe. This anomaly is most often associated with proximal hypospadias. Surgical repair is usually performed during hypospadias repair. The technique is similar to that used for repair of penoscrotal transposition. An alternative is the use of single or multiple Z-plasty procedures to correct the defect (Mokhless et al, 2011) (Fig. 146-19).

Ectopic Scrotum

Ectopic scrotum (Fig. 146-20), the anomalous position of one hemiscrotum along the inguinal canal, is a rare condition. The location can be suprainguinal (most common), infrainguinal, or perineal (Lamm and Kaplan, 1977; Elder and Jeffs, 1982). This anomaly has been associated with cryptorchidism, inguinal hernia, and bladder exstrophy as well as with the popliteal pterygium syndrome (Cunningham et al, 1989). In one review, 70% of boys with a suprainguinal ectopic scrotum exhibited ipsilateral upper urinary tract anomalies, including renal agenesis, renal dysplasia, and ectopic ureter (Elder and Jeffs, 1982). Another study indicated that an associated perineal lipoma was found in 83% of these children; 68% of those with a lipoma had no associated anomalies, whereas 100% of those without a lipoma had associated genital or renal malformations (Sule et al, 1994). Because the embryology of the gubernaculum and of the scrotum are intimately related chronologically and anatomically, the ectopic scrotum may result from a defect in gubernacular formation that prevents migration of the labioscrotal swellings (Hoar et al, 1998). **Patients with an ectopic scrotum should undergo upper urinary tract imaging with ultrasonography.** Scrotoplasty and orchiopexy may be performed at 6 to 12 months of age or earlier if other surgical procedures are necessary for associated anomalies.

Scrotal Hypoplasia

Scrotal hypoplasia, the underdevelopment of one or both sides of the scrotum, occurs most commonly in boys with an undescended testis and in infants with genital ambiguity. The deformity may result from lack of gubernacular swelling of the labioscrotal folds.

Scrotal Agenesis

The absence of the scrotum or hemiscrotum is rare (Fig. 146-21 on the Expert Consult website). There are seven reported cases of scrotal agenesis, all of which included XY karyotype and bilateral undescended testes; the presence of the median raphe; and other anomalies such as cognitive impairment, bilateral nystagmus, cleft palate, and syndactyly (Silay et al, 2013). Two cases of hemiscrotal agenesis have been reported. In one case, multiple anomalies were found; in the second case an isolated hemiscrotal agenesis was reported. In both cases the penis and contralateral hemiscrotum and contents were normal. In addition, the testes on the affected side were in what would have been the normal location (Flum et al, 2012; Yilmaz et al, 2013).

Scrotochisis

Meconium peritonitis may occasionally cause genital manifestations, including meconium hydrocele (Ring et al, 1989) and congenital rupture of the scrotum, termed *scrotochisis* (Gongaware et al, 1991; Salle et al, 1992; Chun and St-Vil, 1997; Kojori and Demaria, 2007; Premkumar et al, 2009). This can result in one or both testes being extruded from the scrotal sac. When scrotochisis is detected the clinician should suspect meconium peritonitis and proceed with the appropriate evaluation. Treatment involves scrotal exploration with orchiopexy and primary closure of the scrotal wall defect (Fig. 146-22 on the Expert Consult website).

The development of the flaps and their rearrangement are seen for a simple Z-plasty (**B**) and multiple Z's (**C**). (From Mokhless I, Youssif M, Eltayeb M, et al. Z-plasty for sculpturing of the bifid scrotum in severe hypospadias associated with penoscrotal transposition. *J Pediatr Urol.* 2011 7:305-9.)

VASCULAR LESIONS OF THE GENITALIA

Vascular lesions of the genitalia are uncommon without a consensus on classification, etiology, and treatment. These deformities include hemangiomas and vascular malformations. **Hemangiomas are on the skin**, are often congenital, and may show significant growth in the postnatal period followed by slow involution. **Vascular malformations are present at birth in the subcutaneous tissues** and tend to persist or to enlarge, which can occur secondary to trauma, sepsis, or hormonal changes (Ramos et al, 1999). **Vascular malformations can be subdivided into either slow-flow (capillary, lymphatic, venous) or fast-flow (arterial, arteriovenous) types.**

Congenital Hemangiomas

Congenital hemangiomas are common and affect the genitalia in approximately 1% of all hemangiomas (Alter et al, 1993). The origin of these lesions and the mechanisms regulating their growth and

involution are controversial (Ritter et al, 2007). Strawberry hemangiomas are the most common type and result from proliferation of immature capillary vessels. These are also categorized as cutaneous hemangiomas because they occur on the skin. Although the lesions may undergo a period of rapid growth lasting 3 to 6 months, gradual involution is common, and most lesions require no treatment (Casale and Menashe, 1989; Girard et al, 2006). If ulceration develops, intervention is necessary to prevent complications from bleeding. The most popular form of therapy is short-term oral corticosteroid therapy. Treatment with laser therapy allows selective photothermolysis and destruction of superficial blood vessels (Kennedy et al, 1993; Ward et al, 1998). In some cases, surgical excision is necessary.

Subcutaneous Hemangiomas

Subcutaneous hemangiomas, also referred to as *cavernous hemangiomas*, are much less common than the cutaneous variety (Sule et al, 1993; Ferrer and McKenna, 1995) and are probably more appropriately

Figure 146-20. Ectopic scrotum.

classified as a vascular malformation. They may be detected at birth or later in life. In contrast to cutaneous hemangiomas, which tend to involute, cavernous hemangiomas tend to enlarge gradually and should be treated with care. Physical examination reveals a “bag of worms” sensation similar to that of a varicocele, although the lesions tend to be firm and do not decompress when the patient is recumbent. Ultrasonography with color Doppler imaging, computed tomography (CT), or MRI is recommended to delineate the size of the hemangioma (Aizenstein et al, 1996) because examination does not disclose the extent of the lesion. Definitive treatment by en bloc resection is advised, and preoperative angioembolization may reduce the size of the mass and the risk of bleeding.

Klippel-Trénaunay-Weber Syndrome

Klippel-Trénaunay-Weber syndrome is a triad of cutaneous vascular malformation, most commonly nevus flammeus, in combination with soft tissue and bone hypertrophy. The anomaly manifests at birth, usually involving a lower extremity, but it may also involve the trunk or face. These vascular lesions have a propensity to bleed. In a review of 214 patients from a single institution, Husmann and colleagues (2005) found that 30% had genitourinary cutaneous or visceral involvement. Of the 48 (22%) who had cutaneous genital involvement, 29% developed intractable bleeding. Excision of the hemangiomas was associated with significant blood loss.

Vascular Malformations

The penis may also be affected by vascular malformations. These lesions are congenital but are usually not diagnosed until the teenage years or young adulthood. The lesions are characterized as a faint blue patch or a soft blue mass. Careful excision is effective (Kaufman et al, 2010) but if the lesion affects the glans penis, the neodymium:yttrium-aluminum-garnet laser may yield a better result (Ramos et al, 1999).

HERNIA AND HYDROCELES

Embryology

Patients with inguinoscrotal pathology, namely inguinal hernias and hydroceles, are commonly referred to pediatric urologists for

diagnostic confirmation and management. The processus vaginalis forms during the third month of gestation as the peritoneum bulges into the inguinal canal just before the onset of testicular descent. On completion of testicular descent, the processus vaginalis obliterates and the portion adjacent to the testes becomes the tunica vaginalis. Obliteration of the processus vaginalis continues postnatally, and its failure to obliterate accounts for nearly all inguinoscrotal abnormalities seen in infancy and childhood. In an autopsy series, Mitchell found closure of the processus vaginalis in 18% of full-term infants at birth (Mitchell, 1939). Among 1965 children undergoing unilateral inguinal hernia repair, Rowe identified a patent contralateral processus vaginalis in 63% of patients younger than 2 months and about 40% of those 1 to 2 years of age, with similar frequency up until age 16 years (Rowe et al, 1969). The incidence of incidental patency observed in older children and adults at autopsy or laparoscopy is about 20% (Ajmani and Ajmani, 1983; van Wessem et al, 2003).

Definitions (Fig. 146-23)

Indirect inguinal hernia: a widely patent processus vaginalis extending beyond the internal inguinal ring containing abdominal contents (bowel, omentum, gonads) which may pass into the inguinal canal, labia, or scrotum

Communicating hydrocele: a patent processus vaginalis extending beyond the internal inguinal ring containing peritoneal fluid alone, which extends to the testis, with fluid within the tunica vaginalis

Hydrocele of the spermatic cord: fluid contained within a segment of patent processus vaginalis with obliterated processus distally and proximally

Scrotal hydrocele: fluid contained within the tunica vaginalis surrounding the testis without communication proximally

Abdominoscrotal hydrocele: a large scrotal hydrocele that extends proximally across the internal inguinal ring into the abdomen without communication with the peritoneum

Epidemiology and Pathogenesis

Inguinal Hernia and Communicating Hydrocele

Inguinal hernias develop in 1% to 5% of children. The incidence is 5 to 10 times more common in boys and significantly more common among premature infants (13% of babies born before 32 weeks and nearly 30% of babies weighing less than 1 kg). The propensity for the right side (3:1) is attributed to the later descent of the right testicle. (Jones et al, 1998; Brandt, 2008). Female gender, prematurity, age younger than 1 year, and history of cryptorchidism are risk factors for bilaterality (Ein et al, 2006; Brandt, 2008). One study suggests a protective effect of breastfeeding against the development of inguinal hernias (Pisacane et al, 1995). Whereas hernias may occur at any time during childhood, the average age at presentation is 3 to 4 years, with nearly one third of cases manifesting before age 6 months (Kapur et al, 1998). Concomitant hydroceles are frequently seen; 19% of 6361 cases were found by Ein and colleagues (2006) (70% scrotal, 26% cord, and 4% both) (Ein et al, 2006).

The majority of new hydroceles occurring after birth and before puberty are associated with a patent processus vaginalis. In an observational study, 59% of 302 newly identified hydroceles in patients 1 to 18 (mean 4.4) years of age were clinically communicating (clear history of fluctuation), and 6% were spermatic cord hydroceles (Christensen et al, 2006). Seventy (65%) of the apparently noncommunicating and 5 (29%) of the cord hydroceles were followed, and spontaneous resolution was noted in 39 and 3, respectively. Among boys undergoing hydrocele repair, complete obliteration of the processus vaginalis was noted in 0% to 22% of cases (Elder, 1992; Barthold and Redman, 1996; Han and Kang, 2002).

Noncommunicating Hydroceles

Hydroceles that spontaneously resolve during infancy or appear during or after puberty are more commonly noncommunicating.

Figure 146-23. Anatomy of the processus vaginalis in hydrocele. A, Normal closure of the processus vaginalis; *straight arrows* indicate the funicular process; *curved arrow* is the tunica vaginalis. B, Communicating hydrocele with complete patency of the processus vaginalis. C, Funicular hydrocele with distal closure of the processus vaginalis; communication with the peritoneal cavity may also result in hernia. D, Encysted hydrocele of the spermatic cord. (From Martin LC, Share JC, Peters C, et al. Hydrocele of the spermatic cord: embryology and ultrasonographic appearance. *Pediatr Radiol* 1996;26:528–30.)

These form from delayed fluid absorption or abnormal fluid dynamics within the tunica vaginalis or less commonly in response to tumor, trauma, or inflammation. Simple scrotal hydroceles occur in at least 5% of male neonates (Osifo and Osaigbovo, 2008) and are typically bilateral, and resolve with fluid reabsorption.

Genetics and Associated Conditions

Please see the Expert Consult website.

Diagnosis

Signs and Symptoms

Inguinal hernias and communicating hydroceles typically manifest as a painless bulge found in the groin or extending along the cord to the scrotum. The bulge may be present only during periods of increased intra-abdominal pressure (crying or bowel movements); the supine position facilitates reduction of peritoneal fluid and intra-abdominal contents. **The presence of an intermittent bulge helps to distinguish a reducible inguinal hernia and communicating hydrocele from a scrotal hydrocele or hydrocele of the spermatic cord.** The child with an incarcerated inguinal hernia will be irritable or inconsolable and have a persistent or larger bulge without spontaneous reduction and may have decreased appetite and signs of bowel obstruction (abdominal distention, vomiting, and lack of flatus or stool).

The scrotal hydrocele may be seen as a chronic or acute scrotal swelling after an inflammatory, infectious, or traumatic event. The hydrocele size is typically stable but may decrease over time. The hydrocele of the spermatic cord is also usually painless and variable in size. It may be confused for the testis because of its round-oval shape.

Physical Examination

Physical examination starts with a child standing, if age appropriate, otherwise supine. Inspection proceeds from the lower abdominal skin crease and along the inguinal canal to the scrotum. If the child is crying, the bulge should be assessed to emerge or increase in size and then improve or disappear when the child is consoled. Techniques to increase intra-abdominal pressure may induce protrusion of the bulge (immobilizing the extremities to induce crying in infants, and jumping, coughing, laughing, blowing bubbles, or

blowing up balloons in older children) (Brandt, 2008). If a bulge is not elicited at the time of examination, photographs of the bulge taken by family members are diagnostically reliable (Kawaguchi and Shaul, 2009).

Palpation proceeds craniocaudally from superior-lateral to the pubic tubercle down to the scrotum to determine the proximal and distal extent of the swelling. Communicating hydroceles and hernias start at the level of the internal ring and end variably. The silk-stocking sign (sensation of rubbing silk together), sought by rubbing the cord structures side to side near the pubic tubercle, implies thicker cord structures. A hydrocele of the spermatic cord may be confused with a testis, but normal cord structures are palpable above and below and a testis will also be palpated. Scrotal hydroceles may elicit a blue hue through the scrotal skin. Normal cord structures are palpable superior to the hydrocele but may be difficult to distinguish if it extends up to or across (abdominoscrotal) the internal ring, in which case abdominal examination should reveal a ballotable mass. The hydrocele fluid surrounding the testicle should transilluminate; however, neonatal bowel may also transilluminate. The testis should be palpable within a soft scrotal hydrocele but may be difficult to discern within a tense hydrocele.

Radiologic Imaging

Imaging is often of limited usefulness. Ultrasonography may identify a large elongated echolucent area from the groin extending anteromedially in the spermatic cord; omentum or bowel with peristalsis can be found in a large hernia sac (Fig. 146-24). **In the presence of a presumed hydrocele, a sonogram can aid in identifying an unpalpable testicle surrounded by hydrocele fluid (Fig. 146-25).**

Surgical Repair

Inguinal Hernia

Inguinal hernias require surgical repair shortly after diagnosis, given the significant risk of associated complications. Outpatient surgery can be performed within a few weeks in easily reducible hernias or communicating hydroceles and more urgently if there is moderate difficulty in reducing the hernia contents. Parental counseling regarding the signs and symptoms of incarceration should occur. An irreducible hernia requires immediate exploration. Hernias in premature infants can be repaired before hospital

A genetic predisposition to developing inguinal hernias exists, and potential genome sites have been identified. Among probands, there is a 28% risk in other family members and a higher relative risk in first-degree relatives (6.9), particularly female siblings (17.8) of affected girls (Gong et al, 1994; Jones et al, 1998). Genetic transmission appears to be autosomal dominant with reduced penetrance. Zheng has implicated DNA sequence variants (DSVs) within T-box transcription factor 1 (TBX1) and TBX2 as rare causes (Zhang et al, 2014a, 2014b). Sezer identified polymorphisms of the collagen type I $\alpha 1$ (COL1A1). The Sp1 binding site was associated with a higher risk of developing inguinal hernias (Sezer et al, 2014).

Hernias are associated with other diseases and anomalies. These include bladder exstrophy, epididymal anomalies, connective tissue disorders, cystic fibrosis, and posterior urethral valves. Inguinal hernia is also a component of over 200 syndromes, many of which have known specific genetic alterations (Winter-Baraitser Dysmorphology Database, www.lmddatabases.com). Other genital anomalies such as polyorchidism, transverse testicular ectopia with or without persistent müllerian ducts, and splenogonadal fusion may be seen at the time of hernia repair. Abnormal epididymal-testicular attachment correlates with degree of closure of the processus vaginalis (Elder, 1992; Barthold and Redman, 1996). Finally, the presence of abdominal ascites or a ventriculoperitoneal shunt increase the chances of developing an inguinal hernia (Grosfeld et al, 1991).

Figure 146-24. Sagittal image of a scrotal ultrasound in a 4-year-old boy with an inguinoscrotal bulge. Bowel is seen within the hernia sac that ends (arrow) superior to the testis (T) in the scrotum.

Figure 146-25. Sagittal (SAG) image from a scrotal sonogram of an 8-month-old boy with tense scrotal swelling and indiscernible testis on palpation. Sonogram demonstrates hypoechoic fluid (hydrocele) surrounding the normal testis.

discharge, but repair may need to be delayed in extremely low-birth-weight (<1500 g) infants or those with congenital heart disease, pulmonary disease, sepsis, or metabolic disease because of the increased risk of anesthesia. Some authors recommend delaying surgery until 50 to 52 weeks postconception rather than performing it before hospital discharge (Stylianios et al, 1993; Chen et al, 2009).

Hydroceles

Hydroceles in infants have the potential to resolve spontaneously. If the hydrocele persists by age 1 or if the hydrocele enlarges during the period of observation, then surgery is indicated. Hydroceles of the spermatic cord do not tend to resolve spontaneously but rarely require urgent surgery and can also be corrected after age 1 year.

Standard Inguinal Hernia Repair

The traditional surgical approach to repairing an indirect inguinal hernia or communicating hydrocele, high ligation of the hernia sac at the level of the internal inguinal ring, carries high success rate, low morbidity, limited postoperative pain, and good cosmesis. A small incision is made in the Langer lines at the skin crease superolateral to the pubic tubercle (Kogan, 2007). The Scarpa fascia is incised to expose the external oblique fascia, which is then cleared laterally and caudally to the external inguinal ring. The external oblique fascia is opened in the direction of its fibers, with care taken to avoid injuring the ilioinguinal nerve. In young infants, the internal and external inguinal rings are in close proximity, providing adequate access without opening of the external oblique fascia (Mitchell-Banks technique) (Kurlan et al, 1972). The cremaster

muscle fibers are separated perpendicular to the cord to expose the hernia sac anteromedially. The sac is elevated and separated from the rest of the cord and then divided between clamps. The proximal side is elevated and separated from the cord proximally to the internal ring, where it is ligated to avoid risk of recurrence (Grosfeld et al, 1991). If there are obvious contents present or if the sac is large or thickened, it should be opened before ligation to confirm the absence of any tissue or to reduce bowel, omentum, or a sliding component. The internal ring should be tightened medially in cases of significant widening (Ein et al, 2006; Brandt, 2008). When the distal sac is short, it may be left in place, and when long, the anterior aspect can be excised. A hydrocele should be excised and any appendages removed.

In peripubertal boys with hydrocele, an inguinal approach is preferred if there is clinical evidence of a communicating hydrocele; otherwise a trans-scrotal hydrocele repair is performed as in adults and an inguinal incision made only if a proximal communication is identified. In a retrospective study, Wilson and colleagues recorded the intraoperative findings of children undergoing hydrocele repair and found hydroceles were noncommunicating in 82.1% of children older than 10 years and in 86.4% of children older than 12 years. Age was significantly associated with a patent processus vaginalis (Wilson et al, 2008).

Complications

Early postoperative complications, including bleeding and infection, are rare after standard hernia repair. The rate of recurrent inguinal hernia after uncomplicated open repair is 0.5% to 1% (Farrow and Thompson, 1963; Grosfeld et al, 1991; Zhang and Li, 1993; Wright, 1994; Vogels et al, 2009) and rises to 2% for premature infants (Krieger et al, 1994; Misra et al, 1994) and 3% to 6% after repair of an incarcerated hernia (Clatworthy et al, 1954; Farrow and Thompson, 1963). Recurrence typically occurs within 1 year for 50% of the patients and by 2 years for more than 75% (Grosfeld et al, 1991; Wright, 1994). The causes of recurrent hernias include failure to properly identify or ligate the sac during the original procedure; a tear in the sac, leaving a strip of peritoneum along the cord; damage to the floor; or a missed direct hernia at the original exploration. Surgical repair of recurrent hernias can usually be accomplished inguinally with ligation of an indirect sac at the level of the internal inguinal ring and/or repair of the floor of the inguinal canal for a direct hernia.

The incidence of complications related to the genital tract, secondary cryptorchidism, testicular atrophy, and vasal injury is not well defined. If a testis is incompletely descended or retractile, orchidopexy should be performed at the time of herniorrhaphy. Iatrogenic cryptorchidism is avoidable (Kaplan, 1976; Puri et al, 1984) by confirming proper testis position on completing the herniorrhaphy. The risk of testicular atrophy was 0.3% in the large single center series (Ein et al, 2006) but ranged from 4% to 12% in other series (Clatworthy et al, 1954; Rowe and Clatworthy, 1970), with higher rates among the irreducible cases (Fasching and Hollwarth, 1989). The causes include compression of the gonadal vessels by the irreducible hernia or vascular damage incurred during surgical repair. Young infants are at higher risk with infarction rates of 30% to 33% (younger than 2 or 3 months) (Slowman and Mylius, 1958; Fasching and Hollwarth, 1989). Portions of vas deferens are found in 0.13% to 0.3% of cases, although embryonal remnants not representing true ductal structures are much more common (1.5% to 2.9%) (Popek, 1990; Partrick et al, 1998; Steigman et al, 1999). The risk of vasal injury may be higher in young infants and/or cases of incarceration. Vasal injury without transection may manifest as vasal obstruction and infertility later in life (Sheynkin et al, 1998).

Persistence of a hydrocele is very rare after decompression at the time of hernia repair (0.1% in the series by Ein and associates [2006]) and should be observed for spontaneous resolution for at least 1 year. If persistent, secondary scrotal hydrocele repair is indicated, or reoperative hernia repair if fluctuation suggests a recurrent hernia.

Figure 146-26. Transinguinal laparoscopic views of (A) a closed (white arrow) and (B) an open contralateral internal inguinal ring. Note the bubbles emanating from the air pushed back through the open ring. (Courtesy Israel Franco, MD.)

Scrotal Approach to Inguinal Hernia Repair

Concurrent with reports advocating a scrotal approach to orchidopexy, some authors suggest a similar approach to inguinal hernia and communicating hydrocele (Lais and Ferro, 1996; Fearne et al, 2002; Gokcora and Yagmurcu, 2003). For bilateral inguinal hernias, Shih described a median raphe approach (Shih and Uen, 2012). Initial data suggest no major differences in success rate or morbidity using the scrotal approach compared with standard inguinal surgery. Fearne and colleagues (2002) ligated the processus vaginalis at the level of the external inguinal ring in 195 boys and saw 1 recurrence (mean follow-up, 13 months). Issues related to the level of sac ligation and patient age have not been fully addressed (Wilson et al, 2008) and deserve longer-term follow-up.

Laparoscopic Inguinal Hernia Repair

Laparoscopic hernia repair using two major techniques—peritoneal closure of the defect (Schier, 2006) and an extraperitoneal approach (Takehara et al, 2006; Endo et al, 2009)—has gained interest. Alzahem performed a meta-analysis of 10 comparative studies of laparoscopic versus open inguinal hernia repair in 2699 infants and children. Laparoscopic techniques were associated with a trend toward higher recurrence rate, longer operative time for unilateral repairs, and shorter operative time for bilateral repairs. There was a significant reduction in development of a contralateral metachronous inguinal hernia in the laparoscopic group (Alzahem, 2011). Surgery can be performed efficiently but the recurrence risk remains higher (up to 4%) than with open repair, although it may decrease with increasing experience (Saranga Bharathi et al, 2008). Conflicting literature exists regarding levels of pain and operative time after laparoscopic repair (Chan et al, 2005; Koi-vusalo et al, 2009).

Please see the Expert Consult website for further details.

Assessment of the Contralateral Internal Ring

The need to assess the patency of the contralateral processus vaginalis or of the internal inguinal ring in children with a unilateral hernia remains controversial. The goal of contralateral assessment is avoidance of metachronous hernia development and its attendant risks and costs. Historically, routine contralateral exploration was performed, and then more selectively in patients considered at high risk for metachronous hernia based on age, prematurity, gender, or associated disease. In a survey, 51% of pediatric general surgeons stated that they routinely perform contralateral exploration in premature infants; 40% perform exploration in boys younger than 2 years, and 13% in boys ages 2 to 5 years (Levitt et al, 2002).

In contrast to older methods, transperitoneal diagnostic laparoscopy offers a rapid, direct, and accurate inspection of the

contralateral internal inguinal ring (Fig. 146-26). A meta-analysis of 964 laparoscopic evaluations identified a sensitivity of 99.4% and specificity of 99.5%. The incidence of an open contralateral internal ring among boys younger than 1 year without a clinical hernia is 10% undergoing laparoscopic orchidopexy (Palmer and Rastinehad, 2008). Among those undergoing unilateral inguinal hernia repair, the incidence of a contralateral patent processus vaginalis ranges from 57% to 68% during open exploration and 39% to 61% during laparoscopic hernia repair (Tepas and Stafford, 1986; Zona, 1996; Miltenburg et al, 1998; Saad et al, 2011). The incidence is inversely related to age; Chin and colleagues (1995) found an open contralateral ring in 41% of infants younger than 1 year, in about 30% of toddlers aged 2 to 5 years, and in 19% of children older than 10 years. The incidence in adults at autopsy is 20% (Ajmani and Ajmani, 1983).

The incidence of metachronous development of an inguinal hernia is low. A meta-analysis by Miltenburg and colleagues (1997) of studies including patients in whom the patency status of the contralateral ring was unknown reported a 7% risk of developing a metachronous contralateral hernia, with 90% developing within 5 years of the initial repair. A systemic review by Ron and associates (2007) confirmed this incidence. Among 1291 children whose contralateral ring was deemed closed by transinguinal laparoscopy, 2.5% had a metachronous contralateral hernia 12.2 months (median) later (Juang et al, 2012), and at the time of unilateral laparoscopic hernia repair 3.1% of 293 children at a median of 24 months of age (range, 6 to 42 months) (Tam et al, 2013). Unfortunately, these studies offer indirect insight into the natural history of an open internal ring, and the question of the natural history of such a ring will remain unanswered until a prospective study of known open contralateral internal inguinal rings is conducted.

Abdominoscrotal Hydrocele

Abdominoscrotal hydroceles are uncommon, accounting for 1.25% of all hydroceles in a large series (Avolio et al, 2000), and are bilateral in about 30% of cases (Ferro et al, 1995; Nagar and Kessler, 1998; Belman, 2001; Bayne et al, 2008; Cozzi et al, 2008). These noncommunicating scrotal masses are tense and extend into the abdomen, where they may be palpable. Ultrasound may aid in defining the proximal extent (Belman, 2001). Abdominoscrotal hydroceles usually manifest in infancy as such or as scrotal hydroceles that enlarge over time (Celayir et al, 2001; Cuervo et al, 2009), improve (Cozzi et al, 2008), or resolve spontaneously (Upadhyay et al, 2006). Associated diagnoses include cryptorchidism, contralateral hernia, hydrocele, or vanishing testis.

The most likely cause is enlargement and extension of a scrotal hydrocele into the retroperitoneal or properitoneal space after closure of the processus. Bayne and associates (2008) found that abdominoscrotal hydrocele fluid was exudative and theorized that

Despite the aforementioned considerations, efforts have been made to reduce the size (Turial et al, 2011b) and number of ports and to apply the techniques to younger and more complex patients. Whereas the standard laparoscopic approach uses three ports, some authors report similar outcomes using two ports (Xu et al, 2013) or even a single port (Shen et al, 2010). Turial and associates (2011a) reviewed their experience in 147 infants who weighed 5 kg or less using either a 5-mm scope or a microlaparoscope and 2-mm instruments. The median operative time for the bilateral hernia was 20 minutes. Hernias recurred in 2%, with a higher risk for those with an American Society of Anesthesiologists (ASA) score of 3 or more. No cases of testicular atrophy occurred, and high testes requiring surgery occurred in 4%, which was inversely related to body weight. Esposito and associates (2010) performed outpatient laparoscopic inguinal hernia repair on 50 children younger than 1 year. After division of the sac distal to the ring, the peritoneum was closed using a purse-string suture of a nonabsorbable material. The median operating time was 22 minutes (unilateral, 7 to 30; bilateral, 12 to 42) with one recurrence. Recurrence rates may be lower in those younger than 1 year than in older children (Choi et al, 2012). Esposito and colleagues (2013) reported their experience with 46 patients with an incarcerated hernia (1 month to 8 years), of which over one half were irreducible. There were no conversions and two recurrences (4.3%) after a minimum follow-up of 14 months. They purport three main advantages of the laparoscopic approach: aversion of edematous tissue by bypassing the cord structures; bowel reduction performed under direct visual control; and inspection of the incarcerated organ at case end.

increasing size and pressure would lead to lymphatic obstruction and progression. Massive enlargement could extend into the upper abdomen and be associated with hydroureteronephrosis, lower extremity edema, or appendicitis (reviewed by [Cuervo et al, 2009](#)). [Chamberlain and colleagues \(1995\)](#) first reported dysmorphic elongation of the testis; this was subsequently confirmed ([Bayne et al, 2008](#)) but found to be reversible in most cases ([Cozzi et al, 2008](#)).

The traditional surgical approach is an inguinal incision with proximal dissection of the sac from its abdominal attachments and distal complete or partial mobilization, with or without orchidopexy. Some authors advocate orchidopexy to avoid iatrogenic cryptorchidism ([Nagar and Kessler, 1998](#); [Bayne et al, 2008](#)). Aspiration of the scrotal component may facilitate the proximal dissection ([Cuervo et al, 2009](#)). Alternative approaches include a midline abdominal approach for large bilateral cases ([Serels and Kogan, 1996](#)) or laparoscopic decompression of the abdominal component followed by inguinal excision ([Abel et al, 2009](#)). To avert injury to the spermatic cord or vas, a strip of the lining of the sac may be left along the cord ([Ferro et al, 1995](#); [Cuervo et al, 2009](#)). Tightening of a patulous internal ring is described, but may be unnecessary because the processus vaginalis is invariably closed.

[Belman \(2001\)](#) described a primary scrotal approach with drainage and extensive plication with limited dissection; excision is performed. [Cozzi and colleagues \(2008\)](#) reported reduced morbidity and similar efficacy for the scrotal (5 patients) approach compared with the inguinal approach (13 patients). Persistent scrotal swelling, hematoma, and undescended and/or hypoplastic testis was reported in 11 inguinal cases and infection in 2 scrotal cases.

ACUTE SCROTUM

Acute scrotum refers to the constellation of new onset of pain, swelling, and/or tenderness of intrascrotal contents. There is a limited differential diagnosis ([Box 146-2](#)) with considerable overlap of signs and symptoms, which may affect the ability to make a definitive diagnosis; some reliable clinical features exist, and adjunct use of scrotal imaging is helpful in making a diagnosis. **Torsion of the appendix testis is the most common diagnosis** (40% to 60%), followed by spermatic cord torsion (20% to 30% excluding neonates), epididymitis (5% to 15%), and other or no pathology (10%) ([Anderson and Giacomantonio, 1985](#); [Sidler et al, 1997](#); [Van Glabeke et al, 1999](#); [Mushtaq et al, 2003](#); [Murphy et al, 2006](#); [Mäkelä et al, 2007](#)). Although all of these diseases can occur at any time during childhood, appendage torsion is typically most common after infancy and before puberty, whereas epididymitis and spermatic cord torsion are most common in the perinatal and pubertal periods. Torsion of an appendage and epididymitis are managed conservatively with limited consequence; prompt surgical exploration for testicular torsion is imperative because the gonad is at considerable risk of ischemic damage or loss, particularly when there is a delay in presentation, evaluation, or management.

Spermatic Cord Torsion

Acute Intravaginal Spermatic Cord Torsion

Predisposing Factors. Intravaginal torsion is commonly attributed to excess mobility of the testis within a “bell-clapper deformity” wherein the tunica vaginalis abnormally fixes proximally on the cord. Although found in 12% of males at autopsy ([Caesar and Kaplan, 1994a](#)), the prevalence of torsion is much lower: 8.6 per 100,000 males aged 10 to 19 per year in the United States ([Mansbach et al, 2005](#)). There is evidence for a familial predisposition ([Cunningham, 1960](#); [Collins and Broecker, 1989](#); [Cubillos et al, 2011](#)) for which the transmission is unknown. [Cubillos and colleagues \(2011\)](#) found a family history (various relatives) in 10% of probands, including one family with three generations of torsion. **The inciting event for torsion is unknown** but may include cold temperature ([Srinivasan et al, 2007](#); [Lyronis et al, 2009](#); [Chiu et al, 2012](#)) or a change in temperature ([Chen et al, 2013](#)) activating the

BOX 146-2 Differential Diagnosis of Pediatric Adolescent Acute Scrotal Pain

Appendage torsion
Appendix testis
Other appendage (epididymis, paradidymis, vas aberrans)
Spermatic cord torsion
Intravaginal, acute or intermittent
Extravaginal
Epididymitis
Infectious
Urinary tract infection
Sexually transmitted disease
?Viral
Sterile or traumatic
Scrotal edema or erythema
Diaper dermatitis, insect bite, or other skin lesions
Idiopathic scrotal edema
Orchitis
Associated with epididymitis with or without abscess
Vasculitis (e.g., Henoch-Schönlein purpura)
Viral illness (mumps)
Trauma
Hematocoele or scrotal contusion or testis rupture
Hernia or hydrocele
Inguinal hernia with or without incarceration
Communicating hydrocele
Encysted hydrocele with or without torsion
Associated with acute abdominal pathology (e.g., appendicitis, peritonitis)
Varicocele
Intrascrotal mass
Cystic dysplasia or tumor of testis
Epididymal cyst, spermatocele or tumor
Other paratesticular tumors
Musculoskeletal pain from inguinal tendonitis or muscle strain
Referred pain (e.g., ureteral calculus or anomaly)

cremasteric reflex, and/or rapid testicular growth at puberty; yet torsion may occur at rest or at sleep. Cryptorchid testes are at increased risk of torsion and difficult to assess because of the high position. Torsion after previous orchidopexy may be related to failure of suture (absorbable or nonabsorbable suture) to fix the testis in place ([Redman and Barthold, 1995](#); [Frank and O'Brien, 2002](#); [Mor et al, 2006](#)).

Clinical Presentation. Intravaginal testicular torsion may occur at any age, but the vast majority of cases occur after age 10 years with a peak at 12 to 16 years ([Anderson and Giacomantonio, 1985](#); [Sidler et al, 1997](#); [Mushtaq et al, 2003](#); [Mansbach et al, 2005](#); [Murphy et al, 2006](#); [Mäkelä et al, 2007](#)). The prevalence of testicular torsion is 1 in 4000 ([Williamson, 1976](#)) with left-sided predominance and rare bilaterality. Classically, boys complain of acute, severe scrotal pain that occurs at rest (even sleep), or with physical activity or after trauma. **A history of prior episodes may be elicited.** Alternatively, patients may have milder, less acute, or even absent scrotal pain or may have inguinal or abdominal pain. Nausea and vomiting occur in 10% to 60% of boys ([Williamson, 1976](#); [Knight and Vassy, 1984](#); [Jefferson et al, 1997](#); [Sessions et al, 2003](#); [Mäkelä et al, 2007](#)). Scrotal edema and erythema may be present, depending on the duration or degree of torsion. Dysuria and fever are uncommon.

The most common physical findings are generalized testicular tenderness, abnormal orientation of the testis, and absent cremasteric reflex. Inspection may identify the high-riding testis from a

foreshortened cord and horizontally oriented testis. The genitofemoral reflex arc, normally present after age 2 years (Caesar and Kaplan, 1994b), is elicited by scratching the inner thigh with resultant testis elevation. Some studies report reduced or absent reflex in all cases of testicular torsion (Caldamone et al, 1984; Rabinowitz, 1984; Kadish and Bolte, 1998), but it was intact in up to 10% of proven cases of torsion in other series (Hughes et al, 2001; Nelson et al, 2003; Karmazyn et al, 2005; Murphy et al, 2006). The presence of a cremasteric reflex correlates with intact testicular blood flow but does not unequivocally indicate normal testicular perfusion, especially if the clinical presentation is otherwise suggestive of torsion. Although anterior epididymal position, thickening of the cord, testicular induration, loss of boundaries between the testis and epididymis, scrotal edema, and/or erythema may be present, landmarks become obliterated and the examination less reliable as the duration of torsion increases.

Several efforts have been made to offer a better clinical assessment of testicular torsion in patients with the acute scrotum. Using a standardized history and physical examination form, Srinivasan and colleagues (2011) found that absence of ipsilateral cremasteric reflex, nausea or vomiting, and scrotal skin changes on multivariate analysis were predictive of testicular torsion. According

to use of a decision tool, patients with acute (<72 hours) scrotal pain and all of the following had no risk of testicular torsion (100% sensitivity and negative predictive value): normal testicular lie, lack of nausea and vomiting, and age 0 to 10 years (Shah et al, 2013). Barbosa and colleagues (2013) developed a scoring system based on testicular swelling, hard testicle, absent cremasteric reflex, nausea or vomiting, and high-riding testis that needs further validation.

Diagnostic Studies. Urinalysis is of limited usefulness in cases of testicular torsion but is used to identify pyuria and/or bacteriuria associated with epididymitis, or hematuria, implicating a urinary tract calculus. Before the advent of reliable and rapid scrotal imaging, immediate scrotal exploration was routine. Radionuclide imaging carried about 90% sensitivity and specificity but was lengthy, was not readily available, and used ionizing radiation and is currently rarely used. Ultrasound offered a rapid, available, and safe modality to assess testicular architecture, intraparenchymal blood flow, and other anatomic details (hydrocele, scrotal thickening).

CDUS findings consistent with testicular torsion include reduced or absent Doppler color or waveforms and parenchymal heterogeneity compared with the contralateral testis (Fig. 146-27). Kaye and

Figure 146-27. Imaging of intravaginal spermatic cord torsion. **A**, Intermittent torsion. Color Doppler ultrasonography (CDUS) demonstrates preserved arterial flow to testis with 12 hours of pain and then loss of flow and parenchymal heterogeneity when child returned later with worsening pain. **B**, Acute torsion with reduced arterial flow. **C**, Prolonged torsion. CDUS shows heterogeneous testis without arterial or venous flow and a hyperechoic parenchymal ring.

colleagues (2008b) and later Chmelnik and colleagues (2010) found that all testes with heterogeneous echogenicity were necrotic, whereas homogeneous echogenicity predicted a lower risk of orchiectomy. Lack of demonstrable intratesticular flow on CDUS is 86% sensitive, 100% specific, and 97% accurate in the diagnosis of torsion and ischemia in painful scrotum (Burks et al, 1990) and its use spread (Kass et al, 1993b), and even current studies reflect the accuracy of this approach. Altinkilic and colleagues (2013) prospectively assessed the diagnostic value of CDUS in patients with clinical suspicion of torsion who were explored by a surgeon blinded to the CDUS results. The sensitivity, specificity, and positive and negative predictive values of CDUS for detecting testicular torsion were 100%, 75.2%, 80.4%, and 100%, respectively. The authors concluded that routine surgical exploration was unnecessary if CDUS reveals normal intratesticular perfusion. However, in other studies the sensitivity in confirming decreased or absent blood flow in proven cases of spermatic cord torsion was only 63% to 90%, possibly because of enhanced detection of flow with newer equipment and/or user-dependent characteristics (Steinhardt et al, 1993; Stehr and Boehm, 2003; Bentley et al, 2004; Kalfa et al, 2004; Karmazyn et al, 2005). Cassar and colleagues (2008) evaluated Doppler waveforms in cases of torsion with decreased or preserved testicular flow and observed subtle waveform abnormalities, including increase or decrease in amplitude relative to the normal testis and reversal of diastolic flow. Increased epididymal size and/or echogenicity and altered epididymal vascularity, usually absent or reduced but occasionally increased, may provide additional support for the diagnosis of torsion (Nussbaum Blask and Rushton, 2006).

High-resolution (10- to 20-MHz probe) ultrasonography (HRUS) of the length of the spermatic cord may enhance the ability to diagnose torsion. Using HRUS to directly image the cord proximal to the testis, Kalfa and colleagues (2004) visualized the cord twist as a 1- to 3-cm snail-shaped mass in 43 patients and a completely linear cord in nontorsion cases. In a multi-institutional retrospective series of 919 cases of acute scrotum with cord imaging by HRUS, a cord twist was seen in 96% of cases of surgically proven torsion, and HRUS carried 99% specificity when the cord was linear (Kalfa et al, 2007). However, Karmazyn and coworkers (2005) observed normal testicular blood flow and no visible spermatic cord twist in 2 of 41 boys with partial or intermittent torsion.

Potentially useful diagnostic modalities include contrast-enhanced pulse-inversion ultrasonography (CEUS), infrared thermography, and scrotal MRI. Pulse-inversion imaging in a rabbit model showed superior quantitative assessment of perfusion of the experimentally torse testis as compared with conventional CDUS (Paltiel et al, 2006). CEUS was performed in 50 patients with acute scrotal pain or trauma in whom testicular lesion of undefined nature was found at CDUS. Sensitivity and specificity were 76% and 45% for CDUS and 96% and 100% for CEUS, respectively (Valentino et al, 2011). Infrared thermography showed significant reduction in scrotal temperature by 1 hour after 720-degree torsion and prompt normalization with detorsion in a sheep model (Capraro et al, 2008). MRI has been used in small series of testicular torsion and may have a role in difficult diagnostic cases with use of dynamic contrast-enhanced MRI, which requires gadolinium (Mäkelä et al, 2011), or diffusion-weighted imaging with findings of a lower testicular apparent diffusion coefficient (ADC) without need for contrast (Maki et al, 2011).

Management and Surgical Treatment

Testicular torsion is a true surgical emergency because testis viability is inversely related to duration of torsion. Visser and Heyns (2003) amassed data from published series including 1140 patients and found the risk of orchiectomy was approximately 5%, 20%, 40%, 60%, 80%, and 90% at 0 to 6, 7 to 12, 13 to 18, 19 to 24, more than 24, and more than 48 hours after onset of pain, respectively. The degree of torsion may provide incomplete vascular occlusion, helping to explain the variability of these data. Orchiectomy after surgical detorsion occurs in 30% to 70% in large

studies (Sessions et al, 2003; Murphy et al, 2006; Mäkelä et al, 2007; Kaye et al, 2008b) and in 32% to 42% in database reviews (Mansbach et al, 2005; Cost et al, 2011; Zhao et al, 2011). Sessions and associates (2003) found that the median degree of rotation was 540 degrees in orchiectomy testes and 360 degrees when the testis was salvaged, with a range of 180 to 1080 degrees in both groups. The risk of delayed atrophy after orchidopexy was less than 10%, 40%, and 75% after less than 12, 12 to 24, and more than 24 hours of pain, respectively (Visser and Heyns, 2003). Partial (<25%) testicular atrophy may occur after operative detorsion even after 4 hours after the onset of pain (Krupar, 1978; Anderson and Williamson, 1986; Tryfonas et al, 1994; Sessions et al, 2003). Preoperative manual cord detorsion may relieve symptoms and allow delayed orchidopexy but may incompletely untwist the cord. Sessions and associates (2003) found that lateral twisting (rather than medial untwisting) occurred in 33% and manual detorsion failed to completely relieve torsion in 32% of orchidopexy cases.

There are two management approaches to the acute scrotum. One is to avoid delay and perform exploration in virtually all boys to confirm absence of torsion; this implies many unnecessary surgeries (Anderson and Giacomantonio, 1985; Watkin et al, 1996; Sidler et al, 1997; Mushtaq et al, 2003; Mäkelä et al, 2007). The other approach is more selective of patients for surgical exploration (Caldamone et al, 1984; Kass et al, 1993b; Kalfa et al, 2004; Lam et al, 2005) based on the history, physical examination, and CDUS findings, which may lead to testis loss because of atypical presentation and/or false-negative imaging. **When findings support or raise suspicion for spermatic cord torsion, emergent scrotal exploration is indicated and should not be delayed.**

Surgical exploration of the testis through a hemiscrotal transverse (dartos pouch) or midline raphe incision should first address the affected side. The testis is delivered and the tunica vaginalis opened to note the color of the testis, the number of rotations, and the anatomy of the tunica vaginalis. The testis is untwisted, wrapped in warm soaked gauze, and observed for improvement in color while the contralateral testis is fixed with nonabsorbable suture to reduce the risk of metachronous torsion. The affected testis is re-examined for potential viability, and the largely subjective decision for orchidopexy or orchiectomy is made. A Doppler flow probe or incision of the tunica albuginea (Arda and Ozyaylali, 2001) with assessment of bleeding may document intratesticular flow after detorsion; however, the reliability of these assessments lacks validation. If the testis is to be retained, it is fixed either via dartos pouch or directly to the dartos with nonabsorbable suture. Kutikov and colleagues (2008) have suggested that a compartment syndrome contributes to testicular injury based on the improved appearance and lower intraparenchymal pressures seen after detorsion and tunica albuginea incision in three cases. A patch of vascularized tunica vaginalis was placed in the tunica albuginea defect to maintain lower intraparenchymal pressure and to reduce the likelihood of ongoing ischemia. Figueroa and colleagues (2012) applied this technique to 11 of 28 testes deemed nonsalvageable at surgery and found that 55% recovered. The long-term outcome of these patients is not available; however, in a rat model of testicular torsion, no significant histologic differences were found between a detorsion group and detorsion with tunica vaginalis flap group after 4 weeks, despite reduction of intratesticular pressure in both groups (Oktar et al, 2013).

Risk factors for orchiectomy include young age, African-American race, and being on Medicaid or lacking insurance (Cost et al, 2011; Zhao et al, 2011). Zhao and colleagues (2011) identified surgery at a children's unit to increase the risk of orchiectomy. This may reflect the transfer of patients, which delayed treatment by 75 minutes in the study by Bayne and colleagues (2010). Orchiectomy is performed by dividing the cord into segments, each of which is ligated with nonabsorbable suture. In cases of orchiectomy, prosthesis placement is usually offered after complete healing or later in puberty; however, Bush and Bagrodia (2012) demonstrated the feasibility of performing concurrent prosthetic placement and orchiectomy.

Prognosis

Although the impact of testicular torsion on fertility is poorly understood given the inherent difficulty of long-term follow-up in these patients, the few available studies suggest that subtle abnormalities of semen quality are common. **Semen density is often within the normal range but correlates with shorter duration of torsion and reduced atrophy** (Puri et al, 1985; Fisch et al, 1988; Anderson et al, 1992; Brasso et al, 1993; Arap et al, 2007). The observation that increasing duration of torsion inversely correlates with semen quality and limited contralateral testicular biopsy data suggest that global testicular dysfunction may exist after torsion (Visser and Heyns, 2003). The hypothesis of an autoimmune phenomenon (Anderson and Williamson, 1990) was dispelled by analysis of antisperm antibodies in individuals with torsion (Puri et al, 1985; Anderson et al, 1992; Brasso et al, 1993; Arap et al, 2007). Available animal and human data support a role for ischemia-reperfusion injury after release of testicular torsion (Kehinde et al, 2003; Turner et al, 2004). Additional clinical data are needed to determine long-term outcome after testicular torsion and the efficacy of any adjunctive treatment. Romeo and colleagues (2010) assessed serum levels of FSH and LH (before and after GnRH stimulation), testosterone, and inhibin B in 20 patients 5 years (mean) after testicular torsion and in 15 age-matched controls. Twelve patients were treated with detorsion and orchidopexy, and 8 underwent orchidectomy. Serum FSH, LH, and testosterone were within the reference range. Inhibin B levels were significantly reduced in the two torsion groups compared with the controls but not between each other.

Intermittent Intravaginal Spermatic Cord Torsion

Episodes of self-limited acute scrotal pain precede acute testicular torsion in 30% to 50% of patients (Williamson, 1976; Stillwell and Kramer, 1986). These episodes, single or multiple, typically begin and resolve acutely with durations of minutes to hours. Hayn and associates (2008) observed that the frequency of these episodes correlated with the risk for eventual persistent torsion and testicular loss; 71% of patients were previously diagnosed with epididymitis or appendage torsion, and 53% had acute or delayed testicular loss. Nausea and/or vomiting or notation of scrotal swelling may or may not be present. A normal vertical testicular orientation is most common (Hayn et al, 2008), but a horizontal lie may be present (Schulsinger et al, 1991). Physical findings consistent with torsion depend on whether the testis is twisted at the time of the examination. This includes the degree of tenderness and cremasteric reflexes. Eaton and colleagues (2005) reported absent cremasteric reflex in 3 of 15 patients and reduced or absent intratesticular blood flow by CDUS in only 5 of 12 patients. A whirlpool sign or an abnormal boggy cord and pseudomass formation below the twisted spermatic cord may also signify intermittent torsion (Munden et al, 2013).

There are challenges to confirming the diagnosis of intermittent torsion. **The diagnosis requires a high index of suspicion unless the testis is noted to untwist during an examination or an ultrasound study shows absent or decreased flow before and normal to increased flow after marked improvement of symptoms.** Once the condition is confirmed or highly suspected, **elective bilateral orchidopexy is indicated** to avert torsion and possible organ loss. Patients and parents should know that absolute confirmation of the diagnosis may not be possible and that symptoms may persist postoperatively.

Extravaginal Spermatic Cord Torsion (Perinatal Testicular Torsion)

Perinatal spermatic cord torsion is a term applied to infants regardless of whether the event occurred prenatally (hours, days, weeks, months), during delivery, or postpartum. Torsion of the entire cord occurs before fixation of the tunica vaginalis and dartos within the scrotum (extravaginal). This event most commonly occurs well

Figure 146-28. Extravaginal spermatic cord torsion in a neonate. Transverse ultrasound image demonstrates enlarged and heterogeneous left testis and bilateral hydroceles.

before delivery, yielding a “vanishing” testis or a hemosiderin-containing nubbin in the scrotum or less commonly in the inguinal canal. The testis that sustains loss of blood supply close to delivery is a hard, painless testis fixed to the overlying erythematous or dark scrotal skin with or without edema. A coexisting hydrocele complicates the examination. The estimated incidence is 6.1 per 100,000 births (John et al, 2008), and familial cases are reported (Castilla et al, 1975). Predisposing factors such as high birth weight and/or difficult delivery are suggested (John et al, 2008; Kaye et al, 2008a) but unconfirmed by controlled studies. In a minority of cases, symptoms occur after a documented normal scrotal examination. Rarely, neonatal intravaginal torsion occurs or infarction occurs without torsion (John et al, 2008). Bilateral torsion was noted in 5% and 22% in two series (Yerkes et al, 2005; Baglaj and Carachi, 2007) and may occur concurrently or metachronously. Several series indicate that bilateral metachronous torsion may occur in boys in whom the primary event occurs prenatally or postnatally (Beasley and McBride, 2005; Yerkes et al, 2005; Al-Salem, 2007; John et al, 2008).

Scrotal imaging may be obtained in cases of suspected perinatal torsion, but its usefulness and reliability are questionable. Prenatal ultrasonography may show torsion (Herman et al, 2002). Postnatal ultrasound may reveal parenchymal heterogeneity, calcification, and absent blood flow (Fig. 146-28) (Arenas et al, 2006). Reported cases of testicular blood flow suggest that postnatal CDUS may be unreliable (Yerkes et al, 2005; Al-Salem, 2007; Cuervo et al, 2007; John et al, 2008). Ultrasound helps to differentiate tumors from torsion (Kaye et al, 2008a), but its reliability in this has also been challenged (Calonge et al, 2004; Al-Salem, 2007).

There is no consensus as to the best treatment of perinatal testicular torsion (Snyder and Diamond, 2010). One side advocates elective exploration because of the unsalvageability in most cases, the rarity of metachronous torsion, and the increased anesthetic risk (Das and Singer, 1990; Brandt et al, 1992; Stone et al, 1995; Kaye et al, 2008a). Others advocate for immediate exploration to offer possible partial or complete testicular salvage (Sorensen et al, 2003; Al-Salem, 2007; Cuervo et al, 2007) and point to cases of unexpected contralateral torsion or atrophy found at exploration (Yerkes et al, 2005; Al-Salem, 2007; Baglaj and Carachi, 2007; John et al, 2008; Roth et al, 2011). Among 110 pediatric surgeons and urologists surveyed in the United Kingdom and Ireland, few (10.9%) used Doppler ultrasound to guide management or to exclude tumor. Although most (74.5%) performed ipsilateral orchiectomy and contralateral orchidopexy (71.9%), few operated emergently because a viable testis was seldom found (10%) and bilateral torsion was even rarer (7 cases). Some (21.8%) avoided contralateral orchidopexy owing to concern for iatrogenic injury (Rhodes et al, 2011). If torsion is suspected after a normal postnatal scrotal examination, then prompt exploration should be performed as

for intravaginal torsion. Some surgeons use a scrotal approach, whereas others advocate an inguinal approach to ligate a patent processus vaginalis and avoid the theoretic risk of trans-scrotal surgery if a tumor is found.

Torsion of the Appendix Testis and Epididymis

Appendage torsion is the most common cause of acute scrotum in prepubertal children. The appendix testis and appendix epididymis are vestiges of embryologic development without known function. The appendix testis (from the müllerian duct) and appendix epididymis (from the wolffian duct) are present in 76% to 83% and 22% to 28% of testes, respectively (Dresner, 1973; Jacob and Barteczko, 2005). The appendix testis, located at the cranial testicular pole or in the groove between the testis and epididymis, and the appendix epididymis, located along the caput, may be sessile or pedunculated. Although the sessile type may be more common (Jacob and Barteczko, 2005), the pedunculated type may be more prone to torsion (Jones, 1962). The cause of torsion is unknown but may be related to anatomy, trauma, and/or prepubertal enlargement.

The peak age at occurrence is 7 to 12 years (mean 8 to 9 years) (Anderson and Giacomantonio, 1985; Mushtaq et al, 2003; Lyronis et al, 2009), but the condition may occur at any age. Symptoms vary with sudden or insidious onset of pain, which may be mild or severe and intermittent with physical activity. Similarly, physical findings depend on the severity of inflammation and duration of symptoms (Rakha et al, 2006). Early on, a “blue dot sign” (Dresner, 1973), a discoloration at the upper pole of the testis representing the ischemic appendage, may be seen through stretched scrotal skin in 0% to 52% of patients (Caldamone et al, 1984; Van Glabeke et al, 1999; Karmazyn et al, 2005; Murphy et al, 2006; Lyronis et al, 2009). Murphy reported a false-positive blue dot sign in a patient with testicular torsion (Murphy et al, 2006). Other early signs include a tender nodule superior to the testis with limited testicular tenderness and symmetrical cremasteric reflexes. However, with longer duration and progressive inflammation, increased swelling and tenderness, lack of distinction between testis and epididymis, and marked scrotal wall edema and erythema may make it difficult to distinguish it from testis torsion or epididymitis.

CDUS rarely demonstrates an abnormal appendage but commonly shows hyperperfusion of the epididymis (Baldiasserotto et al, 2005). The normal appendix testis contains no internal blood flow (Yang et al, 2005), whereas the twisted appendage may appear as an ovoid hyperechoic, hypoechoic, or heterogeneous nodule without blood flow (Fig. 146-29). Park and colleagues (2011) found significant differences in the echogenicity correlated with the duration of symptom: hypoechoic in all 17 boys assessed within 24 hours of symptom onset and hypoechoic (6), isoechoic (4), or hyperechoic (8) after 24 hours.

Because torsion of an appendage is a self-limited process (Koff and De Ridder, 1976), surgery is rarely indicated. Treatment is aimed at reducing inflammation using ice packs and oral anti-inflammatory agents, and limiting physical activity. Surgical exploration is limited to cases in which torsion of the testis is not excluded or, rarely, there is prolonged and severe pain or recurrent episodes.

Epididymitis

Epididymitis, infectious or noninfectious, is a broad category causing an acute scrotum. The incidence is poorly defined (Lau et al, 1997; Merlini et al, 1998; Cappele et al, 2000; Somekh et al, 2004; Al-Taheini et al, 2008; Sakellaris and Charissis, 2008), perhaps because children with a torsed appendage may be diagnosed with epididymitis (Kadish and Bolte, 1998; Lam et al, 2005; Lyronis et al, 2009). In many series, peaks in prevalence occur in infancy and at puberty (Sidler et al, 1997; Mushtaq et al, 2003; Mäkelä et al, 2007).

Classically, the symptoms have a more insidious onset than torsion of the cord or an appendage but may be present rapidly. Fever and dysuria may or may not be present, and nausea is rare. A history of UTIs, urethral discharge, sexual activity, intermittent catheterization (Thirumavalavan and Ransley, 1992), dysfunctional voiding (Bukowski et al, 1995), urethral abnormalities (Karmazyn et al, 2009), or congenital anomalies of the ejaculatory duct (Pimpalwar et al, 2002; Yanai et al, 2005) may be present. There is a continuum on examination from localized epididymal enlargement and tenderness to massively swollen and erythematous hemiscrotum without distinct landmarks. The cremasteric reflex should be intact. Associated pyuria and/or bacteriuria is reported in 20% to 40% of cases (Anderson and Giacomantonio, 1985; Sidler et al, 1997; Mushtaq et al, 2003; Murphy et al, 2006; Mäkelä et al, 2007). CDUS shows increased epididymal size and blood flow as well as in the testis in some cases.

The management goal is to relieve inflammation and any associated infection. Efforts to reduce the inflammation include the use of ice packs, nonsteroidal anti-inflammatory agents, scrotal elevation, and rest to avoid traumatic exacerbation. In the absence of UTI, symptoms improve spontaneously without antibiotics (Lau et al, 1997). In the presence of pyuria, broad-spectrum antibiotics with gram-negative coverage should be used (Siegel et al, 1987), and in some cases intravenous antibiotics and hospitalization may be required. Treatment for sexually transmitted diseases should be considered, as appropriate, in adolescents.

The need to image the urinary tract has become more selective. Siegel and colleagues (1987) found that 47% of prepubertal boys had anomalies (urethral anomalies, ureteral ectopia) on imaging. Other clinical series have documented a low risk of urinary tract

Figure 146-29. Torsion of testicular appendage. Color Doppler ultrasonography demonstrates (A) enlarged and heterogeneous appendage and (B) absent flow despite increased flow to the epididymis and testis.

anomalies in boys with epididymitis, although infants may be at higher risk (Merlini et al, 1998; Sakellaris and Charissis, 2008). Although some findings (pyelectasis, low-grade vesicoureteral reflux) may not directly contribute to epididymitis, other findings (urethral or ureteral obstruction, ejaculatory duct, or vasal anomalies) are important to detect. Some authors recommend renal ultrasonography only (Al-Taheini et al, 2008) or imaging only in recurrent cases (Cappele et al, 2000). However, in a prepubertal child with a positive urine culture, renal ultrasonography and voiding cystourethrography are indicated. In recurrent cases, endoscopy may reveal ejaculatory duct abnormalities undetected on voiding cystourethrography (Pimpalwar et al, 2002; Yanai et al, 2005). Recurrent epididymo-orchitis in these cases may require excision of a utricle or ejaculatory duct cyst with vasovasostomy or vasectomy.

Other Causes of Acute Scrotal Pain

Idiopathic scrotal edema manifests in prepubertal boys with unilateral or bilateral scrotal swelling with minimal or no pain (Klin et al, 2002; Lee et al, 2009). Associated findings may include local spread of erythema or edema to the inguinal or perineal region, inguinal lymphadenopathy, leukocytosis, and/or eosinophilia. The last suggests an allergic origin, although the cause is currently idiopathic. Distinctive characteristics include minimal or no pain, isolated scrotal tenderness, and thickening of the scrotal wall. Because the process is self-limited, no treatment is needed, except perhaps for antihistamines.

Henoch-Schönlein purpura is a systemic vasculitis affecting the skin, joints, gastrointestinal tract, and kidneys. The scrotum is involved in 2% to 38% of cases in the form of tenderness, edema, erythema; testicular hematoma, torsion, or infarction; or cord thrombosis or epididymitis (Turkish et al, 1976; Diana et al, 2000; Ioannides and Turnock, 2001). The typical purpuric rash of the buttocks, perineum, and lower limbs is usually present but may not precede the scrotal findings. Urgent scrotal exploration is indicated if clinical findings suggest concomitant testicular torsion.

Cystic dysplasia of the rete testis may present as acute scrotal swelling and pain (Noh et al, 1999; Smith et al, 2008; Jeyaratnam and Bakalnova, 2010). Rarely, an associated ureteral anomaly may lead to chronic testicular pain (McGee et al, 2009). Ipsilateral renal dysplasia, agenesis, or ureteral anomalies are present in the majority of cases and likely represent maldevelopment of the wolffian duct. Ultrasound will reveal multiple small cysts centrally located in the testis. Treatment is conservative enucleation, which may be associated with recurrence, or observation, which is associated with regression in some cases.

Testicular rupture from trauma may cause acute scrotal pain and swelling and hematocele. CDUS is sensitive in diagnosing testicular fracture. Surgical intervention may be indicated (Adams et al, 2008), or a conservative approach may be considered (Cubillos et al, 2010), reserving surgery for cases of expanding hematoma, symptomatic hydrocele, intractable pain, absent blood flow, or abscess. In their series, Cubillos and colleagues reported excellent outcomes and testis salvage; slow resumption of all physical activities was reported by a minority of patients in this small cohort.

VARICOCELE

Varicocele, an abnormal dilation and tortuosity of the internal spermatic veins within the pampiniform plexus, is common among adolescents and may contribute significantly to the risk of subfertility in adulthood. Its effect on paternity is less clear because about 85% of men with varicocele in population-based studies have fathered children (Pinto et al, 1994; Safarinejad, 2008; Bogaert et al, 2013).

Epidemiology and Pathogenesis

The prevalence of clinically diagnosed varicoceles in adolescents is 8% to 16%, which is similar to the 15% prevalence rates in

adults (Niedzielski et al, 1997; Skoog et al, 1997; Akbay et al, 2000; Stavropoulos et al, 2002; Kumanov et al, 2008; Zampieri and Cervellione, 2008). Thus, the group of adolescents identified as having a varicocele is presumed to be the same group identified as adults, because varicoceles are not known to resolve spontaneously and rarely manifest in older adults.

The frequency and severity of varicoceles vary with age, method of diagnosis, and Tanner development stage. Most varicoceles appear after 10 years of age, progress through puberty, and peak at Tanner stage 3 (Kumanov et al, 2008). Although historically varicoceles were predominantly left sided, recent reports indicate that identification of right-sided varicoceles in boys is increasing. Bilateral palpable varicoceles were repaired in one third of 10- to 24-year-old males by Decastro and colleagues (2009), and CDUS identified subclinical left or bilateral varicoceles in 7% to 17% of cases (Akbay et al, 2000; Pfeiffer et al, 2006; Cervellione et al, 2008). Woldu and associates (2013) identified retrograde blood flow in the right side of 40.3% of 503 adolescents with palpable left-sided varicoceles, of which 44% were subclinical. The clinical implication of these subclinical right-sided varicoceles is unclear. In adults, bilaterality is reported in 15% to 50% of cases (Zini and Boman, 2009).

The pathophysiology of the adolescent varicocele is likely to be multifactorial. The primary factors are believed to be increased venous pressure in the left renal vein, collateral venous anastomoses, and valvular incompetence of the left internal spermatic vein at its junction with the left renal vein. Varicocele progression may be related to continuous or spontaneous rather than Valsalva-induced spermatic venous reflux (Pfeiffer et al, 2006; Cervellione et al, 2008; Zampieri and Cervellione, 2008). The “nutcracker phenomenon” (compression of the left renal vein between the aorta and superior mesenteric artery) may account for the varicocele in some boys (Coolsaet, 1980; Kim et al, 2006). The reports by Sakamoto and Ogawa of higher peak and antegrade flow and venous diameter in the prostatic venous plexus of men with bilateral varicoceles versus controls and men with unilateral varicoceles (Sakamoto and Ogawa, 2008) and those showing increased risk of saphenofemoral junction incompetence (Karadeniz-Bilgili et al, 2003) and varicose veins (Kilic et al, 2007) reflect a more generalized venous abnormality in cases of varicocele. Genetic factors may contribute to the risk; the presence of a varicocele was fourfold to eightfold higher among first-degree relatives of men undergoing vasectomy or male kidney donors, and the incidence was especially high in brothers (Raman et al, 2005; Mokhtari et al, 2008). A tall, thin body habitus (low body mass index [BMI]) is associated with varicoceles in adolescents and adults (Handel et al, 2006; May et al, 2006b; Nielsen et al, 2006; Kumanov et al, 2008; Tsao et al, 2009), perhaps because of increased spermatic vein length and/or hydrostatic pressure, or perhaps resulting from difficulty in identification during physical examination.

Diagnosis and Classification

The vast majority of varicoceles in children and adolescents are identified incidentally by a primary care practitioner. On presentation, some adolescents have made the identification of an abnormality on self-examination or, less commonly (2% to 11%), have concerns regarding discomfort (Zampieri et al, 2008a).

The patient should be examined in both the supine and standing positions. The scrotum is inspected for visible swelling, followed by palpation of the spermatic cord at rest and during the Valsalva maneuver. The clinical grading system defines varicoceles as *grade 0* (subclinical), nonpalpable and visualized only by CDUS; *grade 1*, palpable only with Valsalva maneuver; *grade 2*, easily palpable but not visible; and *grade 3*, easily visible. The veins should decompress in the supine position; failure to do so, particularly on the right side, warrants evaluation (CT or sonogram) for an abdominal or pelvic mass (Roy et al, 1989). Testicular consistency should be assessed; the affected testis may be soft. Measurement of testicular volume is important because it may predicate surgical

TABLE 146-4 Testicular Volumes Based on Tanner Stage

TANNER STAGE	DANIEL ET AL, 1982				ZACHMANN ET AL, 1974	
	LEFT TESTIS (cm ³)		RIGHT TESTIS (cm ³)		TOTAL (mL)	
	MEAN	SD	MEAN	SD	MEAN	SD
1	4.8	2.8	5.2	3.9	6.0	2.6
2	6.4	3.2	7.1	3.9	6.8	3.6
3	14.6	6.5	14.8	6.1	9.3	3.8
4	19.8	6.2	20.4	6.8	12.6	4.2
5	28.3	8.5	30.2	9.6	16.3	4.6
6					18.9	4.0

SD, standard deviation.

intervention. The volumes should be assessed based on Tanner stage (Table 146-4). Volume can be determined using the Prader orchidometer (chain of 12 solid wooden ellipsoids of increasing volumes that are visually compared with the size of each testis), the Takihara orchidometer (15 elliptical rings with inner dimensions corresponding to ellipsoid volumes placed over the widest testis circumference), or by ultrasound (measure length, width, and depth and use one of several formulas). All three techniques are reliable, but **ultrasound is more sensitive in determining differences in left and right testicular size** (Costabile et al, 1992; Chipkevitch et al, 1996; Diamond et al, 2000). In a canine study, the use of ultrasound and the Lambert formula provided the most accurate and precise testicular volume estimates (Paltiel et al, 2002).

The ultrasound criteria for diagnosing a varicocele—spermatic vein diameter and retrograde blood flow—are controversial in adults and more so in adolescents. Niedzielski and colleagues (1997) measured spermatic vein diameter in the standing position and spermatic venous reflux with Valsalva maneuvers in 625 boys with varicoceles and 50 normal controls. They found normal spermatic vein diameter (<2 mm in normal boys) in 95%, 70%, and 4% of boys with grades 1, 2, and 3 varicocele and spermatic venous blood reflux in two thirds of boys with grade 2 or 3 varicoceles; flow velocity measured while the patient was standing correlated with varicocele grade and sperm motility. Kozakowski and associates (2009) found that spermatic venous diameter measured in the supine position was a poor criterion for clinical varicocele and did not predict risk of testicular volume loss, but that peak retrograde spermatic vein flow with Valsalva maneuvers that exceeded 38 cm/sec strongly correlated with testicular volume asymmetry.

Associated Pathologic Processes

There is abundant evidence that a varicocele may alter testicular growth, spermatogenesis, and fertility potential. The cause of testicular injury is presumed to be related to increased scrotal temperature, but the pathogenesis remains poorly understood.

Testicular Hypotrophy

In the absence of sufficient direct insight into the potential for subfertility (i.e., semen analysis) associated with varicoceles in adolescents, most attention has been on testicular hypotrophy as a harbinger of pathology and indirect marker surgical success. A decrease in testicular volume has long been associated with varicoceles (Lipshultz and Corriere, 1977). Steeno and colleagues (1976) confirmed the finding in adolescents with grade 2 (34.4% had decreased volume) and 3 (81.2%) varicoceles. The correlation between varicocele grade and left testicular hypotrophy has been confirmed in some studies (Thomas and Elder, 2002; Zampieri

et al, 2008b) but not others (Alukal et al, 2005; Kolon et al, 2008). Because ipsilateral volume loss may improve or resolve after varicocele repair, it was inferred that hypotrophy reflects significant testicular injury (Lyon et al, 1982; Kass and Belman, 1987). The global impact, and by extension damage, of varicocele was noted by Kass and colleagues (2001), who found significantly reduced right testicular size compared with control values in Tanner stage 4 or 5 boys with grade 3 left varicoceles. Okuyama and coworkers (1988) reported right testicular hypotrophy in 22% of patients with grade 2 or 3 left varicoceles, and lower sperm densities among those with bilaterally small testes. Mean right testicular volume increased significantly after left varicocele repair but not in untreated control groups in several other studies (Laven et al, 1992; Yamamoto et al, 1995; Paduch and Niedzielski, 1997).

Significant hypotrophy is variably defined as a 10%, 15%, 20%, or 2- or 3-mL relative difference in testicular size and is found in 10% to 77% of patients (Lyon et al, 1982; Okuyama et al, 1988; Akbay et al, 2000; Thomas and Elder, 2002; Diamond et al, 2004b; Kolon et al, 2008; Preston et al, 2008). This variability is related to the mode of measurement (see later), referral patterns, and the formula used to determine percent differences. Rapid increases in testicular size may occur as early as 10 years of age and persist until age 19, depending on Tanner stage of pubertal development (see Table 146-3) (Schonfeld, 1943; Rundle and Sylvester, 1962; Zachmann et al, 1974; Daniel et al, 1982; Matsuo et al, 2000). Because size variability can vary widely in individuals (Marshall and Tanner, 1970), longitudinal measurements over several years may more accurately define hypotrophy than isolated measurements, particularly in early puberty.

“Catch-up” growth, defined as normalization of left relative to right testicular size, occurs in 32% to 83% of patients after varicocele repair (Cayan et al, 2002; Greenfield et al, 2002; Yaman et al, 2006; Castagnetti et al, 2008; Feber and Kass, 2008; Decastro et al, 2009; Poon et al, 2009; Zampieri et al, 2009) and in 55% to 70% of boys in various series (Barroso et al, 2009). The hypothesis that postoperative resolution of left testicular hypotrophy reflects improved testicular function is challenged by observations that testicular size differential may improve spontaneously in untreated patients (Paduch and Niedzielski, 1997; Kolon et al, 2008). In contrast, others report worsening or development of significant hypotrophy in 10% to 26% of boys over time (Thomas and Elder, 2002; Zampieri and Cervellione, 2008; Kozakowski et al, 2009). Finally, Diamond and colleagues (2004b) reported no statistical difference in either direction in a longitudinal study. Kocvara and colleagues (2003) posited that lymphatic ligation contributes to increased postoperative testicular volume after lymphatic and arterial ligation, but this was disproved by reports showing no difference in rates of catch-up growth based on lymphatic (Poon et al, 2009) and/or arterial (Barroso et al, 2009) preservation. Laven and associates (1992) noted that varicocele repair increased the volume of small but not normal-sized testes. Postoperative left testicular hypertrophy (>10% size differential relative to the right testis) is attributed to non-lymphatic-sparing procedures or to a rebound effect on spermatogenesis in the affected testis (Gershbein et al, 1999; Cayan et al, 2002; Kocvara et al, 2005).

Significant discrepancy between left and right testicular size remains the primary indication for varicocele correction. Unfortunately, the currently available data are unclear as to the direct relationship between this discrepancy and testicular function with or without correction. **Prospective, randomized studies are needed to clearly establish whether unilateral and/or bilateral testicular hypotrophy or catch-up growth accurately predicts fertility potential in adolescent varicocele.**

Testicular Histology

The histologic effect of varicoceles is better known in adults but is largely absent and inconsistent in adolescents. In adults (reviewed by Hienz et al, 1980), histology findings vary from normal on light

and electron microscopy in all men (Fideleff et al, 2000) or even those with severe hypospermatogenesis (Kass et al, 1987; Aragona et al, 1994) to degenerative tubular changes, altered Leydig cell number, and/or proliferative lesions of the vasculature (Hienz et al, 1980). Hadziselimovic and associates (1995) found abnormal tubular maturation and Leydig cell number in a small series of young men who had testicular biopsies at the time of adolescent varicocele repair; these data failed to correlate with ultimate sperm quality in adulthood.

Hormonal Function

The use of hormonal profiles as a proxy to determine if varicoceles are deleterious to testicular function has been inconclusive. Baseline LH and FSH levels are not consistently different in the presence or absence of varicocele in adolescents (Laven et al, 1992; Yamamoto et al, 1995; Cayan et al, 2005; Ku et al, 2005). Basal and stimulated gonadotropin levels were not consistently different in varicocele patients when compared with controls and did not improve after surgery (Fideleff et al, 2000). GnRH stimulation led to an exaggerated LH and FSH response in about 30% of boys with varicoceles but did not correlate with testicular hypotrophy (Kass et al, 1993a). Inhibin B measurements failed to consistently correlate with testicular size or semen parameters in adolescents (Carrillo et al, 1999; Turkyilmaz et al, 2006; Romeo et al, 2007; Basar et al, 2010). Guarino and coworkers (2003) observed increased LH, FSH, and simulated FSH levels in 20 boys with varicoceles and abnormal semen parameters compared with 56 with normal semen, but this was confounded by 30% of boys with bilateral varicoceles, a history of inguinal surgery, or cryptorchidism.

Semen Quality

Semen quality is considered the most useful indicator of fertility potential despite many variables associated with collection and interpretation in adolescents. **Progressive improvement in sperm quality may parallel testicular growth and sexual maturation, and so semen analyses may be best obtained at stabilization of testicular growth, which may not depend on age.** In a study of 194 boys aged 12 to 19 years, Janczewski and Bablok (1985a, 1985b, 1985c, 1985d) found that ejaculation began at a bone age of 13 years (within 16 months of the onset of puberty), and normospermia was achieved by a bone age of 17. There were boys at Tanner stage 5 with asthenozoospermia and occasional oligozoospermia. Mean testicular size increased with progression in semen quality but showed a large SD in boys achieving normospermia; LH and FSH levels significantly declined with attainment of normospermia.

Reliable standards for semen quality based on Tanner stage or age do not exist, and, therefore, recent studies evaluating semen quality among adolescents with varicoceles depend on comparison with adult standards. In the majority of these studies, at least two semen samples were obtained and World Health Organization criteria were used; however, Tanner stage 5 was not always specified. Christman and associates (2013) recently advocated a single semen analysis, because they found sufficient reproducibility of total mobile count (more variability among other parameters) in adolescents at risk for subfertility (varicocele or cryptorchidism). In two randomized studies comparing treated and untreated patients with controls, no differences were found in semen quality at initial or follow-up analysis between groups, except for a significant postoperative increase in sperm concentrations in the treated group (Laven et al, 1992; Yamamoto et al, 1995), hypothesized to be a rebound in spermatogenesis. Correlations between left or total testicular volume and semen parameters were noted by some investigators (Haans et al, 1991; Paduch and Niedzielski, 1996; Diamond et al, 2007) but not others (Guarino et al, 2003). Recently, Christman and colleagues (2014) reported on 73 patients followed for 2.7 years (median) by serial scrotal ultrasound evaluating testicular size and semen analysis at Tanner 5, around age 18 years. A low total motile count was found

in 48 patients (66%). Testicular volume differential could not predict normal semen volume, density, sperm motility, or total motile count. Total testicular volume from the final ultrasound predicted total motile count. Investigators were unable to correlate postoperative increases in left testicular volume or varicocele grade with semen analysis data in controlled (Laven et al, 1992) and uncontrolled (Cayan et al, 2002; Diamond et al, 2007; Zampieri and Cervellione, 2008) studies. **The available data suggest that trends toward poorer sperm quality may be limited to a subset of affected males with varicocele, but that grade and postoperative testicular catch-up growth do not reliably predict ultimate semen quality.**

Intratesticular Varicocele

In 1% to 2% of adolescents, a varicocele may include an intratesticular component found on CDUS (Diamond et al, 2004a; MacLachlan et al, 2013). The diagnosis is made by identifying venous flow in anechoic structures greater than 2 mm in diameter near the mediastinum testis that increases during Valsalva maneuvers (Bucci et al, 2008). MacLachlan and colleagues (2013) found worsening testicular asymmetry that responded to surgical correction and progressed in one patient who refused surgery; they concluded that surgery was indicated in adolescents with intratesticular varicoceles and testicular asymmetry.

Treatment

Observation remains the approach of choice for the majority of adolescents with varicocele until a surgical indication is present. **Despite the aforementioned limitations regarding testicular hypotrophy, the main indications for surgical intervention remain significant left ($\geq 20\%$) or bilateral testicular hypotrophy, pain, or abnormal semen analysis findings; the last is most reliable in boys of Tanner stage 5 and/or at least 18 years of age.** Pain is a rare indication for surgery, reported in only 2% to 10% of patients in most series, and is relieved by the procedure in 68% to 88% of patients (Zampieri et al, 2008a).

Surgical Repair of Varicocele

Several approaches exist to correct the adolescent varicocele: inguinal or subinguinal, laparoscopic or retroperitoneal, or venographic. The surgical decision revolves around (1) whether to spare the testicular artery and/or lymphatics using the available approaches, and (2) the effect on the rate of recurrence and hydrocele formation (Table 146-5) (Poddoubnyi et al, 2000; Misseri et al, 2001; Greenfield et al, 2002; Esposito et al, 2004; Cayan et al, 2005; Kocvara et al, 2005; Schiff et al, 2005; Yaman et al, 2006; Castagnetti et al, 2008; Feber and Kass, 2008; Glassberg et al, 2008; Barroso et al, 2009; Diamond et al, 2009; Tong et al, 2009). Long-term outcome data are lacking to support any particular approach because the length of postoperative follow-up may be insufficient to identify potential recurrences (Glassberg et al, 2008) or sequelae such as a hydrocele, which may require 2 years or more to develop (Misseri et al, 2001; Esposito et al, 2004; Feber and Kass, 2008). Whereas many hydroceles may resolve spontaneously, up to one half may require formal scrotal repair (Misseri et al, 2001; Esposito et al, 2004; Feber and Kass, 2008; Diamond et al, 2009) or aspiration (Esposito et al, 2004) because of large size or symptoms.

Subinguinal or Inguinal Microsurgical Varicocelectomy

The *subinguinal microscopic approach* provides the advantages of facilitated artery and lymphatic sparing, high rate of success, and low risk of hydrocele but may be time-consuming and requires microscopic surgical skills. The procedure used in children is similar to that used in adults as originally published (see Chapter 25). Use of lower degrees of magnification in adolescents (e.g., loupes) may yield inferior results (Greenfield et al, 2002; Cayan et al, 2005;

TABLE 146-5 Results of Adolescent Varicocele Repair

PROCEDURE	RECURRENCE OR PERSISTENCE	HYDROCELE	TESTICULAR ATROPHY
Open suprainguinal (Palomo)	2%-4%	0%-30% (10%)*	
Laparoscopic:			
Nonlymphatic or artery sparing	0%-9%	11%-32% (7%)*	
Artery and/or lymphatic sparing	1%-7%	0%-4%	
Microscopic subinguinal	0%-10%	0%-6%	Rare
Nonmicroscopic inguinal	7%-33%	8%-14%	
Sclerotherapy	6%-35%	Occasional	Rare

*Number in parentheses refers to meta-analysis of Barroso et al, 2009.

Figure 146-30. Images from a lymphatic sparing laparoscopic varicocelectomy. **A**, Laparoscopic dissector approaches internal spermatic vessels under posterior peritoneum. **B**, Vessels have been isolated and elevated off the posterior abdominal wall. **C**, Individual lymphatic channels have been teased out and will be spared and the veins divided. (Courtesy Israel Franco, MD.)

(Diamond et al, 2009) than use of an operating microscope. The subinguinal approach is associated in rare cases with testicular atrophy (necrosis), which has not been reported for suprainguinal procedures (Diamond et al, 2009).

Retroperitoneal and Laparoscopic Varicocelectomy

The ligation of the internal spermatic vessels above the level of the internal inguinal ring is a simple procedure performed by open or laparoscopic approaches with high success rates but higher rates of hydrocele formation. Mass ligation as described by Palomo (1949), offers a highly successful and efficient surgical result. Although potentially more difficult to isolate the arterial and lymphatic vessels, lymphatic- and/or artery-sparing techniques may reduce the incidence of postoperative hydroceles but have an impact on success rate (Kass and Marcol, 1992) and may not benefit catch-up growth (Fast et al, 2014). Zampieri and associates (2007a, 2007b) reported that sparing the artery was associated with improved semen quality; however, randomized prospective data are lacking that clearly define the effect of artery sparing on testicular function. In theory, testis atrophy may follow spermatic artery ligation in patients with prior inguinal surgery (Skoog et al, 1997) but did not occur after laparoscopic Palomo procedures in a small series (Barqawi et al, 2002). Similarly, testis atrophy may occur after non-artery-sparing varicocelectomy and subsequent surgery that compromises the vasal artery or vein (hernia repair, vasectomy).

The Palomo open procedure is performed through a muscle-splitting incision medial to the anterior superior iliac spine. The peritoneum is mobilized medially to expose the bundle of spermatic

vessels, which are isolated, clipped, or suture ligated and left as such, or the vessels are divided, according to surgeon preference. To reduce the risk of postoperative hydrocele formation, a microscopic lymphatic-sparing procedure through this incision was described by Wong and colleagues, without recurrence (Wong et al, 2009).

Laparoscopic varicocele repair is performed using three ports. The two working ports are placed in variable locations: left midclavicular line inferior to the umbilicus and lower midline/right lower quadrant, or both lower quadrants, or both on the right side at the lateral rectus margin. The peritoneum above the internal ring is opened and the vascular bundle and surrounding tissue are mobilized. To help identify the artery, a laparoscopic Doppler probe or papaverine can be used. The magnification provided by the laparoscope helps to identify lymphatic channels as clear tubular structures accompanying the artery and veins (Fig. 146-30). The use of vital dyes injected into the paratesticular tissue to identify lymphatics has potential technical challenges and risks if the dye is inadvertently injected into the testis (Schwentner et al, 2006; Makari et al, 2007). The vessels may be ligated using permanent sutures or clips and transected using the harmonic scalpel or vessel-sealing devices. To avoid recurrence, vein(s) accompanying the artery should be identified and ligated. Cimador and colleagues (2008) used CDUS to search for dilated, refluxing deferential veins in the iliac fossa, which were also ligated. Injury to the genitofemoral nerve has been reported in a limited number of adolescent and adult series and may be more commonly associated with use of electrocautery (Muensterer, 2008). This complication manifests as postoperative paresthesias along the proximal anterior thigh that slowly resolve over weeks or months.

Sclerotherapy or Embolotherapy

The published experience with intravascular injection of sclerosant or thrombotic material to occlude varicoceles in adolescents has been limited and mainly applied to cases of recurrent or persistent varicoceles (Fig. 146-31 on the Expert Consult website). The benefit of this approach is to identify and classify the venous collateralization as possible routes of outflow and reflux. The agents (3% sodium tetradecyl sulfate or polidocanol, with or without intravascular coils or balloons) can be injected in either a retrograde (Reyes et al, 1994; Mazzoni et al, 1999; Alqahtani et al, 2002; Sivanathan and Abernethy, 2003; May et al, 2006a; Beutner et al, 2007; Granata et al, 2008; Reiner et al, 2008) or antegrade fashion. The benefits of the procedure lie in its minimally invasive approach through a transfemoral venous puncture done under local anesthesia (with or without sedation). However, the procedure has generally inferior success rates compared with surgical (open or laparoscopic) procedures, involves significant radiation exposure, and is unfeasible for technical reasons in 5% to 22% of cases. The follow-up is short in available literature (rarely more than 1 or 2 years), with recurrence rates of 6% to 35%. Self-limiting complications include pain, epididymo-orchitis, phlebitis, or scrotal swelling; partial testicular atrophy and hydrocele occur rarely. Antegrade techniques entail use of a small subinguinal or upper scrotal incision, isolation of a vein or veins amenable to cannulation with or without fluoroscopic confirmation of antegrade flow into the internal spermatic vein, and injection of a sclerosant followed by ligation of the vein (Zaupa et al, 2006; Carmignani et al, 2009). Success rates are reported to be 4% to 12%, lower than for retrograde sclerotherapy, with similar complications.

EPIDIDYMAL AND VASAL ANOMALIES

Congenital anomalies of accessory testicular structures are often associated with primary diseases affecting testicular descent and genital development but may occur as isolated anomalies or as part of syndromes that do not primarily affect the genitalia.

Epididymal cysts are simple cystic structures that may be palpable by the patient or examining physician or found incidentally by ultrasonography (Homayoon et al, 2004). Posey found that over an 8-year period, 14.4% of all boys who underwent scrotal ultrasound had epididymal cyst with increasing incidence with age (35.3% among boys >15 years) (Posey et al, 2010). Epididymal cysts may be clinically indistinguishable from spermatoceles except that the latter occur postpubertally and contain sperm. The pathophysiology of epididymal cysts is unknown but may be related to an altered hormonal environment because they are linked to diethylstilbestrol (DES) exposure (Palmer et al, 2009). These lesions are different ultrasonographically and pathologically from the multicystic, solid epididymal cystadenomas that occur in von Hippel-Lindau disease (Choyke et al, 1997). Homayoon and associates (2004) observed spontaneous resolution of many cysts in their pediatric series, and surgical intervention is rarely needed.

Congenital absence of the vas deferens (CAVD) is in most cases associated with specific mutations of the cystic fibrosis gene *CFTR* (cystic fibrosis transmembrane regulator) that are less severe than those encountered in patients with cystic fibrosis (Kolettis and Sandlow, 2002). The disease can be bilateral (CBAVD) or unilateral (CUAVD) with a normal or obstructed contralateral vas and may be associated with renal agenesis or ectopia and/or partial or complete agenesis of the epididymis and seminal vesicles. *CFTR* mutations are more common in males with CBAVD, and renal anomalies are more common in cases of CUAVD. These patients typically have infertility. Abnormal vasal development may also result in a **persistent mesonephric duct** anomaly that is associated with ipsilateral renal and seminal vesicle agenesis and vasoureteral fusion (Kajbafzadeh and Payabvash, 2006). Reflux into the fused wolffian remnants results in UTI and epididymo-orchitis. Other associated anomalies

may include imperforate anus, hypospadias, tracheoesophageal fistula, tetralogy of Fallot, or coarctation of the aorta.

Hypospadias Reoperations

Adult Outcomes after Prepubertal Repair

Improving Outcomes

Hypospadias refers to a urethral opening proximal to the normal glanular location. The defect is commonly considered arrested development, even though embryo penises do not exhibit a similar-appearing phase. Correction is surgical and includes not only urethroplasty but also straightening ventral penile curvature, circumcision or prepuceioplasty, and scrotoplasty with the goal to restore as normal function and appearance as possible.

We discuss hypospadias from a surgical perspective in this chapter, with sections discussing preoperative assessment, intraoperative decision making and management, postoperative care, and complications and their reoperations. Given that complications from initial surgery increase the risk for subsequent complications, we have described operative techniques in detail, emphasizing key steps to reduce the likelihood that additional surgery will be needed. Within each section we briefly recount the best studies available and summarize this evidence in bold type.

PREOPERATIVE ASSESSMENT AND MANAGEMENT

Diagnosis

Hypospadias is diagnosed by physical examination. Typically preputial development is asymmetrical, with a dorsal “hood” and ventral deficiency that exposes the glans and proximal meatus (Fig. 147-1). Other abnormal ventral findings potentially include downward glans tilt, deviation of the median penile raphe, ventral curvature (VC), scrotal encroachment onto the penile shaft, midline scrotal cleft, and penoscrotal transposition.

The main differential diagnosis is *chordee without hypospadias*, which refers to asymmetrical preputial development with a normal glanular meatus. The term implies ventral penile curvature, although in the majority of cases apparent downward bending is corrected simply by degloving the ventral skin. This categorization has included patients with a glanular meatus but deficient corpus spongiosum and a thin distal urethra that others consider a hypospadias variant. To end confusion, boys with a hooded prepuce and bending should be diagnosed with congenital VC if the urethra is grossly normal, or otherwise with hypospadias (Snodgrass, 2008).

Some hypospadias variants present with a normal foreskin concealing a glanular to distal shaft meatus. These generally have a deeply grooved urethral plate, which sometimes extends laterally under the skin edge creating a phenotype known as the megameatus with intact prepuce (Fig. 147-2). The diagnosis of these variants is made after circumcision or when the foreskin becomes retractable.

Prevalence and Inheritance

Hypospadias occurs in 1 in 300 males (0.3%). Recurrence risk is approximately 13 times greater in first-degree relatives (brothers, fathers, offspring).

Several birth registries suggested an increasing prevalence in the 1990s, possibly linked to environmental toxins, but changes in reporting criteria and accuracy of the diagnosis potentially account for these observations.

Three case-control studies of births in Denmark, France, and Italy reported prevalence of hypospadias in 0.3% to 0.45% of male births. The relative risk for recurrence in first-degree relatives was 13 times greater, found in 9% to 17% of brothers and 1% to 3% of fathers. Risk in same-sex twins was 50%. Recurrence risk in offspring was the same as in first-degree relatives (Calzolari et al, 1986; Stoll et al, 1990; Schnack et al, 2008).

Isolated versus Syndromic Hypospadias

Approximately 90% of hypospadias cases are isolated penile defects.

Case-control studies indicate that in most patients hypospadias is an isolated anomaly (Calzolari et al, 1986; Stoll et al, 1990). Syndromic hypospadias is suspected with development delay, dysmorphic facies, and/or anorectal malformation. Examples include:

- **Smith-Lemli-Opitz syndrome**—results from an autosomal recessive mutation of the *DHCR7* gene on chromosome 11q13 coding for 7-dehydrocholesterol reductase. Affected individuals have mental retardation, facial dysmorphism, microcephaly, and syndactyly.
- **WAGR syndrome (Wilms tumor, aniridia, genital anomalies, mental retardation)**—results from a deletion in chromosome 11p13.
- **G syndrome (Opitz G/BBB syndrome)**—occurs from X-linked mutations in the midline-1 gene or autosomal dominant deletions in chromosome 22q11. The resultant phenotype includes hypertelorism, tracheoesophageal defects, cleft lip/palate, and mild mental retardation.
- **Wolf-Hirschhorn syndrome**—derives from deletions in chromosome 4p resulting in mental retardation, seizures, abnormal facies, and midline defects.
- **13q deletion syndrome**—characterized by mental retardation, facial dysmorphism, imperforate anus, and hypospadias with penoscrotal transposition.
- **Hand-foot-uterus syndrome**—an autosomal dominant condition caused by mutations in the *HOXA13* gene on chromosome 7p14-15, resulting in bilateral thumb and great toe hypoplasia.

Disorders of Sex Development

Disorders of sex development (DSDs) are possible in phenotypic boys with both hypospadias and undescended testes, which is considered an indication for karyotyping. The most common diagnosis is mixed gonadal dysgenesis, followed by ovotesticular DSD.

Isolated hypospadias is not considered a DSD. The coexistence of hypospadias with undescended testes may indicate a DSD, especially when there is proximal hypospadias and a nonpalpable testis, although the prevalence is difficult to determine from published reports, which are all retrospective and subject to selection bias for evaluation. Reasons for evaluating some but not other patients with hypospadias and undescended testes were not described in the articles summarized here.

For example, a review by [Kaefer and colleagues \(1999\)](#) identified 79 male-appearing patients with both hypospadias and undescended

testes of whom only 54 (68%) were evaluated by karyotyping. Of the 79 patients, 23 (29%) were diagnosed with a DSD, comprising mixed gonadal dysgenesis ($n = 11$), ovotesticular DSD ($n = 5$), 5α -reductase deficiency ($n = 2$), Klinefelter syndrome ($n = 2$), and partial androgen resistance ($n = 3$).

Two other studies concerning hypospadias with undescended testes similarly reported karyotyping in 42% and 57% of patients, finding either autosomal or sex chromosome anomalies in 17% and 24%, respectively. Of the total of 157 patients represented in these two reports, mixed gonadal dysgenesis occurred in 5 and ovotesticular DSD in 1 ([McAleer and Kaplan, 2001](#); [Cox et al, 2008](#)).

We harvest tunica vaginalis to cover the neourethra in all primary proximal and staged reoperative repairs, and have occasionally encountered an ovotestis fully descended in the scrotum in phenotypic boys with 46,XY karyotype. In such cases we remove the ovarian tissue and explore the contralateral testis then or subsequently.

Imaging

Isolated hypospadias, regardless of severity, is not considered an indication for urinary tract imaging.

One prospective study in Saudi Arabia obtained intravenous pyelography and voiding cystourethrography in patients less than 2 years of age, reporting results in 153 boys with glanular to perineal hypospadias over an 11-year period ending in 1983. Of these, 36 (24%) had abnormal findings, including vesicoureteral reflux ($n = 18$) and a variety of upper urinary tract conditions, including horseshoe kidney, solitary kidney, ureterovesical junction obstruction, and ureteral duplication. Surgery was thought to be indicated in 18 of the 36 patients (12%) (Moore, 1990).

Two retrospective series obtained intravenous pyelography or renal sonography in 41% and 72% of patients, both reporting 18% to be abnormal. Possibly significant findings of hydronephrosis occurred in 4% and 1% (Lutzker et al, 1977; Friedman et al, 2008). Voiding cystourethrography in 163 cases, of which 47% were penoscrotal, diagnosed vesicoureteral reflux in 6 patients (4%) and bladder diverticulum in 2. There was no mention of prostatic utricle (Friedman et al, 2008).

We do not obtain either renal sonography or voiding cystourethrography in boys with nonsyndromic hypospadias, regardless of its severity.

Age for Surgery

Hypospadias repair can be performed as an outpatient procedure in otherwise healthy full-term babies 3 months of age or older.

Considerations in determining the timing of operation include anesthetic risks, psychosexual factors, and the potentially varying risk for urethroplasty complications at different ages.

Anesthetic Risks

Bush and colleagues (2012) reported no unplanned hospital admissions for anesthetic complications in 230 babies 3 to 5 months of age, in whom bronchospasm was documented in the anesthetic record in 5 cases (2%). Preterm babies can undergo outpatient surgery after 56 gestational weeks.

Psychosexual Risks

The American Academy of Pediatrics recommended surgery be completed by age 18 months to limit psychosexual stress ("Timing of elective surgery," 1996). However, a study that used questionnaires and a standardized interview by a psychologist to compare patients ages 6 to 17 years operated before versus after 18 months found no differences in health-related quality of life, psychological adjustment, gender-role behavior, or penile self-perception (Weber et al, 2009).

Urethroplasty Complications

Various reports suggest urethroplasty complications increase with increasing patient age, although the time at which this increased risk occurs is not clear. In contrast, our data question if age is an independent risk factor for complications. This subject is discussed later under Risk Factors in the section on Complications.

Preoperative Androgen Stimulation

Androgens increase penile length and glans circumference, with varying duration of effect after stimulation ends. Only two studies concern the impact of preoperative androgen therapy on urethroplasty complications, one finding a significant reduction in those treated and the other reporting complications remained increased in those stimulated to increase glans size versus those having the same glans size without treatment.

Androgens are documented to increase penile length and glans circumference. However, only one published trial reports the impact

of therapy on urethroplasty complications. Otherwise, most series used subjective criteria in selecting patients for stimulation, used empirical treatment regimens, and had no objective end point.

We (Bush et al, 2013; Snodgrass et al, 2014b) found that urethroplasty complications increased in patients with glans width less than 14 mm, and based on that observation instituted a protocol using testosterone cypionate intramuscular injections to increase width to 15 mm or greater. Of 62 consecutive boys with midshaft and proximal hypospadias, 5 of 15 (33%) and 29 of 47 (60%), respectively, were treated. Initially testosterone 2 mg/kg was given for two or three injections, with all midshaft cases but only 43% of proximal cases achieving the desired glans width, indicating relative androgen resistance. The protocol was changed to administer an escalating dose of testosterone from 2 to 32 mg/kg per injection based on remeasurement 1 month after each injection.

Next Bush and colleagues (2013) analyzed urethroplasty complications in patients who received adjuvant testosterone injections versus those with glans 14 mm or greater who did not. Mean glans width before stimulation was 12 mm, increasing to a mean of 16.5 mm with testosterone injections. Untreated patients had a mean glans width of 15.4 mm. Urethroplasty complications occurred in 34% with versus 11% without adjuvant androgens ($P < .0001$). Because the goal of therapy was to reduce complications, we stopped preoperative testosterone stimulation.

In contrast, a trial by Kaya and coworkers (2008) randomized 75 consecutive boys of mean age 33 months (range 10 to 159) to preoperative topical dihydrotestosterone (2.5% to glans and shaft daily for 3 months) versus no therapy. Treated versus control patients had coronal (70% vs. 84%), penile (24% vs. 16%), and penoscrotal (5% vs. 0%) hypospadias, and all underwent tubularized incised plate (TIP) urethroplasty. Chi-square analysis reported fewer urethroplasty complications in those patients receiving adjuvant stimulation (1 of 37 vs. 9 of 38, $P = .01$).

Hypospadias Encountered During Newborn Circumcision

Caregivers desiring newborn circumcision should be assured that the newborn with a normal prepuce can undergo the procedure without concern for a concealed hypospadias, and that circumcision should not be stopped if hypospadias is encountered.

Original descriptions of the megameatus intact prepuce variant warned that circumcision should be avoided when this variant is discovered, although a review of the literature found no case mentioned in which the prepuce was needed for repair. We have been referred infants whose circumcision was stopped when the practitioner erroneously thought there was a urethral defect, requiring general anesthesia to complete the procedure. An evaluation of concealed hypospadias repair in those with versus without prior circumcision found no difference in urethroplasty complications. Therefore there is no reason to stop circumcision in a newborn with a normal prepuce even if a concealed hypospadias is suspected (Snodgrass and Khavari, 2006).

INTRAOPERATIVE ASSESSMENT AND MANAGEMENT

General Aspects of Surgical Repair

Sutures

There is no evidence that suture materials impact urethroplasty complications.

Guarino and associates (2009) compared primary distal TIP fistula rates for two types of sutures, randomizing 100 boys to either polyglytone (rapid absorption) or polydioxanone (slow absorption). All operations were done by one surgeon, performing urethroplasty in two layers using running subepithelial stitches. Follow-up assessment was blinded to suture type. At 2 years after repair there was no difference in the fistula rates: 4 of 50 (8%) with polyglytone versus 6 of 50 (12%) with polydioxanone.

We prefer 7-0 polyglactin for urethroplasty because the TG-140 needle is significantly smaller than the needle available on 7-0 polydioxanone.

Perioperative Antibiotics

There are no trials concerning preoperative antibiotics before hypospadias surgery. A single trial reported that febrile urinary tract infection (UTI) was reduced by postoperative oral antibiotics.

Meir and Livne (2004) randomized 101 patients undergoing TIP urethroplasty to intraoperative intravenous cefonicid versus intraoperative cefonicid plus postoperative oral cephalexin 3 times daily for 8 days during urinary diversion. Urethroplasty complications were the same, but febrile UTI occurred less often in those treated with oral antibiotics (3 of 52 vs. 12 of 49, $P < .05$).

We do not use preoperative antibiotics except when harvesting oral mucosa, in which case we administer intravenous cefazolin. Patients with postoperative urinary diversion are given trimethoprim-sulfamethoxazole during catheterization.

Nerve Blocks

One randomized controlled trial (RCT) reported penile block to be superior to caudal nerve block for distal hypospadias repair. Penile engorgement was more likely after caudal blocks.

A double-blind RCT by Kundra and colleagues (2012) allocated 54 boys ages 4 to 12 years with distal hypospadias to either penile or caudal nerve block using 0.25% bupivacaine after induction of general anesthesia. Duration of surgery was similar in both groups at 68 ± 15 minutes. A significant mean arterial pressure increase occurred after surgical incision in the caudal versus penile block groups, although only 1 patient was considered to have a failed block. Duration of block was significantly (82 minutes) longer in the penile versus caudal group (302 ± 25 minutes vs. 220 ± 23 minutes, $P = .00$) and there was 43% less postoperative morphine use after penile block. Penile engorgement was determined by measuring stretched penile length and midshaft circumference before and 10 minutes after block. Mean penile volume increased 27% with caudal versus 2.5% with penile block ($P < .001$) (Kundra et al, 2012).

For distal hypospadias we use a dorsal penile nerve block supplemented by a second midline scrotal injection, because infrapubic blocks do not reach sensory branches innervating the ventral midline penis and scrotal and perineal area (Kundra et al, 2012). Caudal nerve blocks are used in proximal cases. When a caudal block cannot be performed, penile and scrotal blocks are used, with a wider area of infiltration at the scrotal base and an additional region of injection superolateral to the scrotum on the side where tunica vaginalis will be harvested.

Urethral Plate Assessment

One study found poor agreement between surgeons judging urethral plate suitability for TIP urethroplasty from photographs. Three studies reported that designation of the urethral plate groove as flat, intermediate, or deep did not predict urethroplasty complications.

Perhaps inevitably, some surgeons wish to rate urethral plate "quality" as a factor in their selection of surgical technique. When done, such subjective assessment makes comparisons between series difficult because various surgeons likely would characterize the plates differently. Supporting this concern was a study by El-Hout and colleagues (2009) involving 21 pediatric urologists who were asked to review photographs and rate the suitability of the urethral plate for TIP urethroplasty using a Likert scale. The authors found poor to slight agreement between the responses regardless of meatal location (distal, midshaft, proximal) or years of surgical experience ($\kappa = 0.06$).

Three studies characterized the urethral plate groove as flat, intermediate, or deep, finding no differences in distal TIP urethroplasty

Figure 147-3. Urethral plate unsuitable for tubularization. The arrow indicates unilateral absence of the corpus spongiosum. Tubularized incised plate urethroplasty was considered a poor option without the usual subepithelial tissues comprising the urethral plate.

complications (Holland and Smith, 2000; Sarhan et al, 2009; Snodgrass et al, 2010). Two of these studies reported that urethral plate preincision width less than 8 mm predicted increased urethroplasty complications. In one the final neourethra calibrated to less than 6 French in 19% of cases (Holland and Smith, 2000), which we suspect indicates inadequate midline TIP incision. In the other both distal and midshaft patients were included (Sarhan et al, 2009), but the results were not adjusted for meatal location, which also impacts outcomes. We are currently measuring urethral plate width at its widest point under stretch and find that only 10% are greater than 8 mm. If TIP urethroplasty is contraindicated by width less than 8 mm, reported complications should be much greater.

Snodgrass and colleagues (2010) reported outcomes in 551 consecutive boys presenting with distal hypospadias. Only TIP urethroplasty was done, with no contraindication encountered. Similarly we have used TIP urethroplasty for nearly all proximal cases with VC less than 30 degrees regardless of the appearance of the urethral plate. In 7% of proximal cases there was intraoperative recognition of rigidity or deficient subepithelial tissues for tubularization (Fig. 147-3) (Snodgrass and Bush, 2011). Admittedly this is subjective, so we emphasize our intention to use TIP urethroplasty in all primary proximal hypospadias cases in which the urethral plate is not transected to achieve penile straightening.

Ventral Curvature

Prevalence

Only 10% of distal hypospadias cases have VC that is less than 30 degrees after degloving. Approximately 50% of proximal hypospadias cases have either no VC or VC less than 30 degrees after degloving, whereas the other 50% have greater than 30 degrees after degloving.

Preoperative assessment cannot accurately predict either the extent of curvature or the means required for straightening. Apparent bending may improve or resolve as the skin is degloved, so the common maneuver of compressing penopubic and penoscrotal tissues at the base of the penis to better visualize the penile shaft may falsely suggest or exaggerate VC by traction on deficient ventral skin. The finding that skin adjacent to the meatus may retract as far as the penoscrotal junction during degloving provides additional proof that relatively short ventral skin contributes to curvature.

Snodgrass and colleagues (2010) performed artificial erection in 440 boys with distal hypospadias after degloving, finding VC that was less than 30 degrees in 11% and lateral bending in another 2%.

In no case was bending greater than 30 degrees by visual estimation. Snodgrass and Prieto (2009) studied 70 consecutive boys with proximal shaft to perineal hypospadias. Nineteen percent had no VC and 31% had less than 30 degrees bending after the penis was degloved and scrotal attachments were dissected. The other 50% had curvature greater than 30 degrees.

These reported degrees of curvature were derived by visual estimation without objective measurement, which we have found cumbersome to perform. Few publications regarding VC report using protractors to accurately determine degrees of bending.

Significance

Several studies of men with Peyronie disease or congenital curvature report that those desiring surgical straightening had 25 degrees or greater bending (Savoca et al, 2000; Gholami and Lue, 2002; Greenfield et al, 2006).

Artificial Erection

Heparinized saline injected into the corpora was first described by Gittes and McLaughlin (1974) to create an erection intraoperatively in men with Peyronie disease, and subsequently was adapted for use in boys with hypospadias.

We perform artificial erection during hypospadias repair after degloving, dissection of ventral dartos, and release of the corpus spongiosum wings from the underlying corpora cavernosa and glans wings in proximal hypospadias because shortened ventral shaft skin, dartos, and spongiosum can contribute to apparent VC. Normal saline is injected into a single corpora using a 23-gauge butterfly needle until erection is achieved. We do not use a tourniquet because occasionally it can mask curvature if positioned at the point of bending. If compression is needed to slow fluid outflow and obtain erection, manual pressure is applied below the base of the penis, pressing the corpora against the crura.

Criticisms of saline injection include supraphysiologic or subphysiologic intracorporeal filling that would over- or underestimate curvature. Vasoactive drugs have also been injected to induce erection during hypospadias repair (Perovic et al, 1997; Kogan, 2000), with the proposed advantage of being a more physiologic assessment in contrast to saline injection. We have no experience with this method.

Means for Correction

VC less than 30 degrees is straightened by dorsal plication. VC greater than 30 degrees after degloving, dissection of ventral dartos and scrotal attachments, and division of the corpus spongiosum wings near their fusion with the glans wings next leads to urethral plate transection and dissection to the meatus. Persistent VC greater than 30 degrees can be corrected by ventral corporotomies with or without grafting.

We correct VC less than 30 degrees with a single midline dorsal plication using either 5-0 or 6-0 polypropylene. Should plication fail, this extent of VC is unlikely to hinder sexual activity. We do not use multiple plications to straighten VC greater than 30 degrees out of concern that results may not be durable into adulthood. Rather, when VC greater than 30 degrees persists after the penis is degloved, ventral dartos dissected, and corpus spongiosum released from the corpora and its fusion to glans wings, the urethral plate is transected at the corona and freed proximally to the meatus. Then artificial erection is done and persisting VC less than 30 degrees is corrected by dorsal plication, whereas VC greater than 30 degrees leads to three transverse corporotomies through the area of greatest bending.

Although single corporotomy with grafting can also be done for ventral lengthening when VC exceeds 30 degrees, this limits urethroplasty options to flaps because a urethroplasty graft placed onto a corporal graft may not take. Because we choose not to perform flap urethroplasties, we lengthen the shortened ventral tunica albuginea of the corpora using three corporotomies without grafting.

Figure 147-4. Midline dorsal plication. The surface of the corpora cavernosa is exposed in the midline opposite the region of curvature, avoiding the dorsal veins, and then polypropylene suture is placed, burying the knot.

Surgical Technique

Dorsal Plication. Midline plication is illustrated in Figure 147-4. Artificial erection identifies the point of greatest bending, and the Buck fascia is incised there longitudinally to expose the underlying tunica albuginea. A single 6-0 or 5-0 polypropylene stitch plicates the midline septum of the corpora, burying the knot. Repeat erection confirms straightening. We do not perform multiple plications.

Results. Recurrent VC was reported in two series in 7% of patients. One stated that all recurrences occurred in plications done for VC greater than 30 degrees. Penile shortening less than 0.5 cm occurred in adults having a mean of three plications.

Two retrospective studies using 5-0 (one also used 4-0) polypropylene both reported recurrent VC in 7% of patients during median follow-up of 16 months (Chertin et al, 2004) and 6 years (Bar Yosef et al, 2004). Chertin and colleagues (2004) did not state the extent of VC, whereas Bar Yosef and associates (2004) used one or two midline plications for VC estimated as less than 30 degrees in 47%, from 30 to 45 degrees in 44%, and greater than 45 degrees in 9% of patients. All patients with recurrent VC had greater than 30 degrees initially, including two of four with VC greater than 45 degrees (Bar Yosef et al, 2004).

One retrospective study involved 154 men with either Peyronie disease or congenital curvature who had objective measurement of both curvature and penile length before and after straightening (Greenfield et al, 2006). Mean curvature determined intraoperatively using papaverine and saline injection and measured using a protractor was 45 degrees (range 25 to 105) for Peyronie disease and 57 degrees (range 25 to 90) for congenital curvature. An average of three plications (range one to six) was done. Mean penile length loss was 0.36 cm (range 0 to 2.5). Although it is frequently stated that dorsal plication shortens the penis, this study suggests that any loss in length is likely subclinical.

Figure 147-5. A, Ventral corporotomies to straighten curvature greater than 30 degrees. B, Three transverse corporotomies are made just through the tunica albuginea from 4 to 8 o'clock (arrows). Then the urethroplasty graft is placed over these incisions.

Ventral Corporal Lengthening. There are two methods for ventral corporotomy. Results appear equivalent, but options for subsequent urethroplasty are impacted by which technique is used.

A single ventral corporotomy can be made from 3 to 9 o'clock though the area of greatest bending. The opening in the tunica albuginea is patched using a graft. Reported materials for grafting include dermis from the groin (hernia-like incision), small intestine submucosa, and tunica vaginalis (as either a graft or flap). Incision with grafting requires flap urethroplasty because a graft urethroplasty would involve placing the urethroplasty graft onto the corporal graft, which likely would not adequately revascularize.

Alternatively, the ventral corpora can be incised from 4 to 8 o'clock beginning through the point of greatest curvature and then making similar incisions approximately 4 mm distally and proximally for a total of three (Fig. 147-5). These incisions through the tunica albuginea are not grafted, and so a urethroplasty graft can be placed directly over them.

Results. Retrospective studies all find recurrent curvature in less than 10% of patients following ventral lengthening by single corporotomy with grafting. One study reported no difference in outcomes from single corporotomy with grafting versus three corporotomies without grafting. One adult with corporotomy plus grafting before puberty reported erectile dysfunction requiring vasoactive drugs.

Snodgrass and Prieto (2009) reported outcomes in 18 consecutive boys with proximal hypospadias, the first 7 having corporotomy with dermal grafting and the next 11 having three transverse corporotomies without grafting. There was no recurrent curvature with either method during follow-up of 27 and 19 months, respectively. This observation demonstrates that corporotomies for ventral lengthening do not require grafting.

Results of single corporotomy with grafting suggest there is little difference in recurrent curvature regardless of the material used to graft the defect. For example, three reviews concerning dermal grafts reported no recurrent curvature requiring additional straightening during follow-up of 2 to 10 years (Pope et al, 1996; Caesar and Caldamone, 2000; Badawy and Morsi, 2008). Badawy and Morsi (2008) studied 16 postpubertal men after prepubertal corporotomy with dermal grafting and stated that one of the three who reported sexual activity needed vasoactive drug corporal injections to maintain a sufficient erection. To our knowledge there are no other reports of erectile dysfunction after incision with grafting, and the authors stated that this individual recovered natural erections after their publication (Badawy, personal communication).

Both single-ply and 4-ply small intestine submucosa have been used for corporal grafting. Of three reports, two observed no recurrent VC during follow up of 1.5 to 3 years (Weiser et al, 2003;

Elmore et al, 2007). A third review after 4-ply grafting stated that 17% of patients had either recurrent VC or a palpable fibrotic mass deemed necessary to excise (Soergel et al, 2003).

Three studies found recurrent VC in 10% or less of patients following grafting using tunica vaginalis (Perlmutter et al, 1985; Ritchey and Ribbeck, 2003; Kajbafzadeh et al, 2007). One other study used tunica vaginalis as a flap with similar results (Braga et al, 2007).

The "Thin" Urethra

The urethra proximal to the meatus may appear "thin" for a varying distance owing to absent or deficient dartos and corpus spongiosum covering (Fig. 147-6). Management depends in part on whether a surgical plane can be established to separate the overlying shaft skin from the urethra, and also on the extent of VC when present. Most often the "thin" segment is only a few millimeters long and the shaft skin can be separated from it. In that circumstance urethroplasty is not influenced except that spongioplasty can be done to cover the thin-appearing region. When shaft skin cannot be separated from the urethra, the "thin" urethra is split down the midline proximally until normal spongiosum is encountered, and then the still-attached skin is incorporated into the neourethra. In the presence of VC greater than 30 degrees after degloving, the urethral plate and the "thin" urethra are excised as part of the straightening process.

Algorithm for Hypospadias Urethroplasty

Figure 147-7 shows the algorithm for hypospadias repair based on tubularization of the urethral plate or a neoplate substitute. All hypospadias can be repaired using either of two operative techniques: TIP and two-stage graft urethroplasty. Inlay graft procedures are a variation on TIP urethroplasty. Two-stage grafts use prepuce or oral mucosa depending on clinical circumstances (discussed later).

Flap options are shown in Figure 147-7 with dashed lines. A comparison of flaps versus grafts is summarized later. We choose to not use flaps because cosmetic results appear to be inferior to these other alternatives.

Distal Hypospadias Repair

Tubularized Incised Plate Urethroplasty

Indications. Snodgrass and colleagues (2010) used TIP urethroplasty as the only repair for 551 consecutive patients with distal

Figure 147-6. Sounding the distal urethra. A, Adequate subepithelial tissues between the shaft skin and urethra (arrow). Initial skin incision can be made 2 mm proximal to the meatus. B, Deficient subepithelial dartos and spongiosum between shaft skin and urethra (arrow). Initial U-shaped skin incision should be made lateral and proximal to the visible urethra.

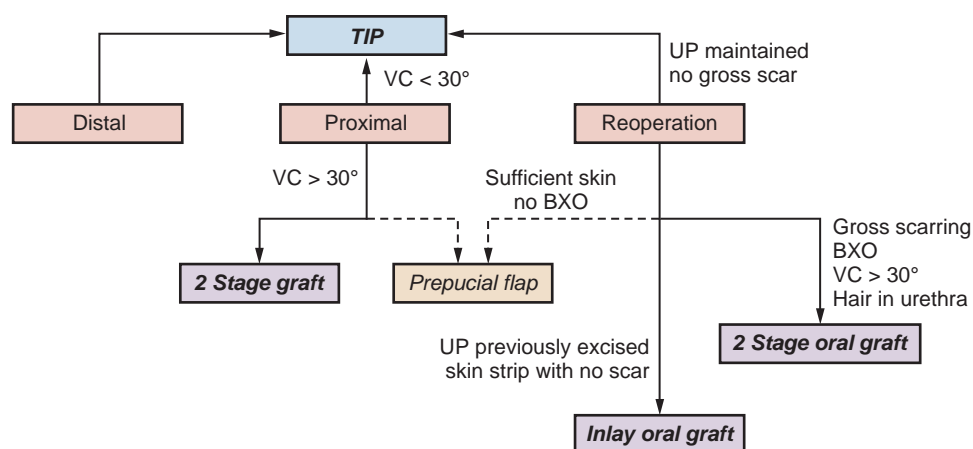

Figure 147-7. Algorithm for hypospadias urethroplasty. BXO, balanitis xerotica obliterans; TIP, tubularized incised plate; UP, urethral plate; VC, ventral curvature.

hypospadias, finding no contraindication to the technique. As discussed in the earlier [Urethral Plate Assessment](#) section, three studies reported no difference in TIP outcomes whether the groove was deep, intermediate, or flat (Holland and Smith, 2000; Sarhan et al, 2009; Snodgrass et al, 2010). Two of these stated that a narrow plate (<8 mm) increased complications (Holland and Smith, 2000; Sarhan et al, 2009), but we believe this indicated failure to adequately incise the plate.

Surgical Technique (Fig. 147-8). Skin management varies according to family preference for circumcision versus prepucioplasty. Because most request circumcision in the United States, we illustrate that method in this section and describe prepucioplasty separately later.

The glans width is determined at its widest point using calipers (Fig. 147-9) and then a 5-0 polypropylene stay stitch is placed. The corners of the dorsal prepuce are held and the line for incision is marked. Ventrally the incision is approximately 2 mm below the meatus, or more proximal if the distal urethra is found by sounding to appear “thin” from deficient underlying dartos and corpus

spongiosum (Fig. 147-10). For glanular cases without fusion of the glans wings, the incision is made a few millimeters below the corona. The oblique dorsal incision is made to preserve sufficient inner prepuce to transfer ventrally and create a uniform “collar” resembling a normal circumcision (Firlit, 1987).

Degloving is done in different planes: dorsally along the Buck fascia and ventrally just under the shaft skin, preserving available dartos. Dissection continues to the penopubic and penoscrotal junctions. Artificial erection is done, and if curvature less than 30 degrees is demonstrated it is corrected by dorsal plication as described earlier.

Next a tourniquet is placed at the base of the penis and the visible junctions of the glans wings to the urethral plate are marked. These lines are injected with 1:100,000 epinephrine and incised using a Beaver 69 blade (Beaver-Visitec International, Waltham, MA). Dissection continues down to the surface of the corpora and then laterally on each side to approximately 3 and 9 o'clock. If the glans width is less than 14 mm, or if there is tension on glans wings approximation after this “standard” mobilization, then additional

Figure 147-9. Measuring glans width. Glans width less than 14 mm predicts increased urethroplasty complications.

“extended” dissection is next done at 3 and 9 o’clock, further releasing the wings for a distance of approximately 4 mm distally (Fig. 147-11).

The urethral plate is held on either side and gently stretched laterally using 0.5 Castroviejo forceps. Tenotomy scissors incise the midline from within the meatus to the tip of the plate down to the

surface of the underlying corpora. Depth of incision varies according to the preexistent plate groove; a flat plate requires a deeper dissection than an already deeply grooved plate. Distal plate incision may leave a small shelf at the glans junction but should not extend into the glans, which is distinguished by its more dull and granular appearance (Fig. 147-12).

A 6-Fr stent is passed into the bladder and tied to the glans traction suture. Urethral plate tubularization is done in two subepithelial layers using 7-0 polyglactin on a TG-140 needle. The first stitch is placed distally approximately 3 mm below the end of the plate to create an oval, not a rounded, opening. Suturing further distally increases risk for iatrogenic meatal stenosis. Continuous stitching proceeds proximally to the meatus where it is tied, and then the same suture returns distally for the second layer. Next a ventral dartos flap is raised, split into two longitudinal segments when possible, and crossed over the neourethra to provide two-layer coverage. We tack this into place using 9-0 polyglactin.

Glansplasty approximates the wings with 6-0 polyglactin subepithelial interrupted stitches, beginning distally and continuing to the corona proximally. Most often three stitches are placed. It is not necessary to additionally suture the epithelium, which could leave visible marks. If there is tension on this closure after usual glans wings mobilization, the stitches are removed and an extended mobilization is done as described previously. The glans wings are not sutured to the underlying neourethra even though there is a gap between the tubularized end of the urethral plate and the first distal stitch of the glans that creates the neomeatus (Fig. 147-13). This gap heals spontaneously.

Residual ventral shaft skin attached to the inner prepuce is then excised and the “collar” approximated using 7-0 polyglactin interrupted subepithelial stitches (see Fig. 147-10C and D), and usually a single epithelial 9-0 polyglactin stitch at the corona. The dorsal prepuce is split in the midline to the edge of the inner preputial collar and then fixed in the midline using a 7-0 polyglactin subepithelial stitch. The ventral midline skin is closed to re-create a median raphe, and remaining excess skin laterally on either side is excised

to complete circumcision. All skin edges are closed with subepithelial stitches. We use urinary diversion into diapers for approximately 1 week.

Alternative Methods. Multiple methods have been described for distal hypospadias that remain in use in various centers. Descriptions

are available elsewhere. The most common include the meatal advancement and glanuloplasty incorporation (MAGPI) and Mathieu or flip-flap techniques.

The MAGPI procedure is an operative technique for glanular and coronal hypospadias in which the urethral plate is cut in the dorsal

Figure 147-12. Urethral plate incision extends deeply to near the corpora, from within the meatus to the end of the plate distally (arrow).

Figure 147-13. Tubularized incised plate (TIP) glansplasty. The most distal stitch approximating glans wings, creating the neomeatus, usually is beyond the most distal stitch of the tubularized urethral plate. It is not necessary to suture the glans wings to the urethral plate in TIP repair.

midline and then the dorsal meatus is advanced distally and sutured. Next the ventral lip of the meatus is pulled distally and the glans closed beneath it (Duckett, 1981).

The Mathieu procedure, or flip-flap, is an operative technique for distal hypospadias in which a rectangular flap is outlined proximally from the meatus on the ventral penile shaft, and then elevated and sutured distally to the urethral plate (Mathieu, 1932). This repair is typically stented for a short period.

Results. Most articles report complications in less than 10% of cases after distal TIP urethroplasty.

Snodgrass and colleagues (2010) reported outcomes in 426 boys a mean of 8 months after distal TIP repair had been performed by Snodgrass. Assessment included calibration, uroflowmetry, and/or urethroscopy done in 279 patients (65%). Urethroplasty complications occurred in 19 patients (4%), including nine fistulas, nine glans dehiscences, and one meatal stenosis that developed later from balanitis xerotica obliterans (BXO). There were no strictures or diverticula.

A systematic literature review by Wilkinson and associates (2012) included 15 articles on distal TIP urethroplasty from 1994 through 2009, comprising 1872 boys. The authors reported 4% fistulas and 3% meatal stenoses with no urethral strictures. Glans dehiscence was not reported.

Snodgrass (2011) also reviewed 36 articles on distal TIP urethroplasty published in English between 1994 and 2009. Reported complications ranged from none to 24%, with 25 of the articles reporting 10% or less, mostly fistulas and meatal stenoses.

Proximal Hypospadias Repair

Decision Making

Choice of technique for proximal hypospadias repair is largely determined by the extent of VC after degloving and excision of any scrotal extensions onto the penile shaft. Options for urethroplasty when there is curvature less than 30 degrees include TIP repair and onlay preputial flap. Curvature greater than 30 degrees resulting in transection of the urethral plate for straightening limits urethroplasty options to single-stage tubularized preputial flaps, two-stage preputial flaps, or two-stage preputial graft repairs.

Tubularized Incised Plate Urethroplasty

Indications. Proximal TIP urethroplasty can be done when there is VC less than 30 degrees. Greater curvature prompts urethral plate transection and so precludes TIP repair. As discussed in the earlier [Urethral Plate Assessment](#) section, in approximately 7% of cases the plate lacks sufficient subepithelial tissues to tubularize, or is subjectively rigid and therefore unsuitable to fashion the neourethra.

Surgical Technique (Fig. 147-14). Proximal TIP urethroplasty can be done with either circumcision or prepucioplasty. In this section we describe the operation as performed when circumcision is requested by the family; prepucioplasty is discussed later.

The glans width is first measured and then a 5-0 polypropylene stay stitch is placed. The dorsal line for incision extends adjacent to the corona approximately 3 mm proximally, preserving most of the inner prepuce for use as a graft should there be either VC greater than 30 degrees or a urethral plate not suitable for TIP urethroplasty. Ventrally the incision runs in a U shape alongside the plate, avoiding visible hair follicles, and then continues down the midline of the scrotum. The ventral incision lines adjacent to the urethral plate are injected with 1 : 100,000 epinephrine to minimize bleeding from underlying corpus spongiosum. The penis is degloved to the penopubic and penoscrotal junctions. All ventral dartos and scrotal attachments are dissected off to the base of the penis.

Next the glans wings are marked along their junction with the urethral plate and also injected with 1 : 100,000 epinephrine before incision. The glans wings are dissected laterally along the surface of the corpora cavernosa to 3 and 9 o'clock. In patients with a glans width less than 14 mm or with tension of glans wings approximation, dissection is extended along the corporal bodies distally for about 4 mm (see Fig. 147-11). The attachments of the corpus spongiosum wings to the ipsilateral glans wings on either side are divided. The spongiosum on either side of the urethral plate is further dissected off the corpora cavernosa for subsequent spongioplasty.

Artificial erection is done and VC is addressed as discussed earlier. When the penis is straight and the urethral plate conserved, the plate is incised dorsally from the meatus to its distal end extending to near the underlying corporal bodies. A 6-Fr stent is passed into the bladder and tubularization is done in two subepithelial layers, the first using an interrupted 7-0 polyglactin stitch and the second a continuous 7-0 polydioxanone stitch.

Spongioplasty approximates the corpus spongiosum wings over the neourethra. Then a hemiscrotum is entered and the testis exposed. The tunica vaginalis is opened transversely and stay stitches are placed into its distal corners. A stay is also placed in the adventitia near the inferior pole of the testis for countertraction. A tunica vaginalis flap is created by dissecting along the spermatic cord to near the external ring. Fatty scrotal tissues are excluded

Figure 147-14. Proximal tubularized incised plate repair. A, Circumscribing incision preserves urethral plate in patient desiring circumcision. B, After degloving, glans wings are separated from the urethral plate. Corpus spongiosum is dissected from the cavernosal bodies and released distally from the glans wings for later spongioplasty. At this point artificial erection is performed and ventral curvature straightened as discussed in the text. C, Midline urethral plate incision. D, Two-layer urethral plate tubularization using interrupted subepithelial 7-0 polyglactin followed by running 7-0 polydioxanone. E, Spongioplasty approximates divergent corpus spongiosum over the neourethra, before a tunica vaginalis barrier flap is added. (From Snodgrass WT. Snodgrass technique for hypospadias repair. *BJU Int* 2005;95:683–93.)

(Fig. 147-15). The testis is returned to its normal position and suture pexed into place, and then its compartment is closed. The flap is brought over the neourethra, shiny surface down, and tacked with 7-0 polydioxanone.

Glansplasty is done in one layer using 6-0 interrupted subepithelial polyglactin, usually with three stitches from distal to the corona. As described for distal TIP urethroplasty, the glans wings are not sutured to the neourethra.

Shaft skin attached to the inner prepuce ventrally is excised (see Fig. 147-10C) and the preputial collar is completed using interrupted subepithelial 7-0 polyglactin and one epithelial 9-0 polyglactin suture at the corona. Then the dorsal prepuce is divided in the midline to the level of the preputial collar and sutured there using 7-0 subepithelial polyglactin. Ventrally the penoscrotal junction typically is incised to approximately 3 and 9 o'clock and then the scrotum near these points is sutured to the corpora on either side of the true penoscrotal junction with 5-0 polydioxanone, moving the tunica vaginalis flap aside to do so. In nearly all cases this maneuver corrects penoscrotal transposition without need for scrotal flaps and the visible scars those produce (Fig. 147-16).

Excess preputial skin is excised to complete the circumcision and the ventral skin is closed, creating a median raphe. All skin stitches are subepithelial. We use urinary diversion into diapers for 2 weeks.

An example of the final cosmetic appearance is shown in Figure 147-17.

Results. Urethroplasty complications have been reported in from 15% to over 50% of cases. One report described technical modifications in the urethroplasty that reduced complications.

Snodgrass and Bush (2011) reported outcomes in 59 consecutive patients, with urethroplasty complications occurring in 53% of the initial 15 cases, 25% of the next 20, and 13% of the last 24. Most of these were fistulas or glans dehiscences, and various technical changes were made specifically to reduce fistula occurrence, including a change from single-layer to two-layer urethroplasty, epithelial to subepithelial suturing, and 7-0 chromic catgut to polyglactin and polydioxanone. All of the first 35 patients had a dartos flap placed over the neourethra. The final 24 had tunica vaginalis rather than dartos flaps. There were no fistulas in the final cohort. Glans dehiscence is now our most common complication, and is discussed in detail later in this chapter.

A report by Ghanem and Nijman (2010) concerned 49 patients with proximal TIP repair in which urethroplasty was done in one layer using continuous subepithelial 6-0 polyglactin covered by dartos. During mean follow-up of 3 years there were urethroplasty complications in 12% of patients that included four fistulas, one meatal stenosis, and one glans dehiscence.

Figure 147-15. Tunica vaginalis barrier flap. A, Testicle delivered and tunica vaginalis opened transversely. B, Tunica vaginalis flap dissected to near the external ring to avoid tension on either the testicle or the penis. C, Flap covers the entire neourethra. Testicle is pexed into its scrotal compartment.

A retrospective review by Braga and associates (2008) compared 35 proximal TIP repairs to 40 onlay preputial flap repairs with mean follow-up of 3 years. There was no significant difference in urethroplasty complications: 60% for TIP and 45% for onlays.

Two-Stage Graft

Indications. The main indication for a two-stage graft repair is VC greater than 30 degrees after degloving and excision of ventral dartos and scrotal attachments to the penis. The urethral plate is transected as part of the straightening maneuvers, and either preputial or oral labial graft is used to bridge from the native urethra to the glans tip. The choice of graft is determined by the family's

preference for either circumcision or prepucioplasty. When circumcision is done the discarded prepuce is used for urethroplasty, whereas oral mucosa from the lower lip is taken when prepucioplasty is desired.

Surgical Technique

First Stage. The initial skin incision is the same as described earlier for proximal TIP urethroplasty, maintaining most of the inner prepuce for a graft if needed. The operation proceeds as described for proximal TIP urethroplasty to the point that artificial erection demonstrates VC greater than 30 degrees.

Urethral plate transection is done distally at the coronal level, and then the plate is excised from the corpora, moving proximally to the meatus and beyond toward the membranous portion. The native urethra is then gently stretched distally and anchored at intervals to the corpora using 6-0 polydioxanone. This maneuver moves the urethrostomy distally, reducing the length of graft needed. The native urethral mucosa is sutured to the corpora using 7-0 polyglactin at 10, 12, and 2 o'clock. Proximal urethroplasty is completed by suturing the native urethra to penile skin or scrotum at 4, 6, and 8 o'clock with 7-0 polyglactin.

Stay stitches are placed into the corners of the dorsal prepuce and the underlying dartos is excised. Typically the graft is mostly inner prepuce with less outer preputial skin, with the width determined by the lower edge of the subcoronal collar (Fig. 147-18).

The dorsal shaft skin is sutured to the preputial collar using interrupted subepithelial 7-0 polyglactin. Then the graft is placed into the ventral defect and first stitched to the glans, which has been opened widely, at the level of the corona with 7-0 polyglactin. Additional stitches secure the graft to the distal end of the glans, placed subepithelially to avoid marks where the neomeatus will be created during the second procedure. The graft is gently stretched proximally and sewn to the shaft skin on either side using interrupted 7-0 polyglactin. The proximal end is split in the midline to extend graft to either side of the urethrostomy, which is sutured at the 2, 10, and 12 o'clock positions medially and to the shaft skin or scrotum laterally. A preputial graft harvested as described in Figure 147-28 (see later) will fill the defect from the glans tip to deep within the scrotum.

Next the graft is quilted onto the corpora at 1-cm intervals using 6-0 polyglactin on an RB-1 needle, which easily penetrates the graft and adheres it to the underlying tunica albuginea (Fig. 147-19). A catheter is placed in the bladder. Then a rolled Vaseline gauze (Conopco, Englewood Cliffs, NJ) is laid onto the graft and held firmly, but not tightly, by 5-0 polypropylene stay stitches tied over the gauze. This tie-over bandage further immobilizes the graft and helps prevent seroma or hematoma accumulation beneath it. The catheter and tie-over bandage are maintained for 7 days. Physical activity is not limited in infants and young children. No special care is needed for the graft after the bandage is removed during the interval before the second stage. We always wait 6 months before second-stage repair.

Second Stage. An incision is marked along the glans wings and shaft skin adjacent to the now revascularized graft, moving into the urethrostomy ventrally to remove the penile or scrotal skin that was sutured there from 4 to 8 o'clock. The glans wings are injected with 1:100,000 epinephrine and incised and dissected laterally, as is the remainder of the marked incision. If the glans width is less than 14 mm, extended dissection is done as described earlier to reduce tension on the subsequent approximation of its wings.

A 6-Fr stent is passed into the bladder and secured to the glans traction stitch. Preputial grafts are very thin and can be tubularized in two layers similarly to the urethral plate in proximal TIP repair using 7-0 polyglactin and polydioxanone. Then a tunica vaginalis flap is created and placed over the entire neourethra. Glansplasty is completed as described earlier for proximal TIP urethroplasty.

A subepithelial 5-0 polydioxanone suture secures the scrotum to the corpora on either side of the neourethra to establish the penoscrotal junction, and then penile and scrotal skin are closed in the midline using subepithelial sutures. Urine is diverted for 2 weeks.

Results. There are few published results for two-stage primary graft repairs, with urethroplasty complications reported in from 25% to 50% of patients.

A retrospective review of 34 patients with proximal shaft to perineal hypospadias operated using two-stage preputial grafts reported urethroplasty complications in 26%, comprising four glans dehiscences,

two fistulas, one diverticulum, and one neourethral stricture (Ferro et al, 2002).

We currently have unpublished follow-up results in 24 patients with proximal shaft (n = 3), penoscrotal (n = 6), scrotal (n = 7), and perineal (n = 8) hypospadias. Ventral lengthening using transverse corporotomies without corporal grafting was needed after

Figure 147-20. Onlay preputial flap. A, Lines of incision to create the preputial flap and preserve the urethral plate. B, Preputial flap mobilized on its vascular pedicle. C, Flap sewn to the urethral plate.

urethral plate transection in 20 (83%). Three patients (12.5%) had graft contracture requiring regrafting as a separate procedure, two involving lip grafts and one after preputial grafting. Urethroplasty complications occurred in 12 patients (52%): 11 glans dehiscences and 2 fistulas. Mean glans diameter for the entire group, measured in 22 patients, was 12 mm, with 15 (68%) less than 14 mm. Extended glans wings mobilization was not used in any of these patients because we had not yet started using this technique.

Preputial Flaps

Indications. Onlay and tubularized preputial flaps are single-stage alternatives to TIP and two-stage graft repairs, respectively.

Surgical Technique

Onlay Flap. The technique for onlay preputial flaps is illustrated in Figure 147-20. The initial lines of incision, degloving and release of dartos and scrotal attachments, and development of glans wings are the same as described earlier for proximal TIP urethroplasty. Artificial erection demonstrates 30 degrees or greater VC, straightened by dorsal plication when present.

The corners of the dorsal prepuce are held with stay stitches and a 10-mm-wide strip of its inner surface is harvested, preserving the underlying dartos vascular supply. Dissection of the pedicle extends to the penopubic junction to prevent tension when the flap is moved ventrally either around the side of the penis or via a buttonhole incision over the glans.

A 6-Fr stent is passed into the bladder. The flap is then sewn to the urethral plate using subepithelial 7-0 polyglactin, gently stretching it distally and trimming it as needed to maintain uniform dimensions. The dartos pedicle is used to cover the suture lines. Next, glansplasty first secures the glans wings to the flap edges using interrupted subepithelial 7-0 polyglactin. Proximally the wings are approximated together with interrupted subepithelial 6-0 polyglactin. Circumcision and skin closures are done as described for proximal TIP urethroplasty.

Tubularized Flap. The technique for tubularized preputial flaps is illustrated in Figure 147-21. When artificial erection finds VC greater

Figure 147-21. Tubularized preputial flap. A, After degloving and release of ventral dartos, persisting ventral curvature greater than 30 degrees led to excision of the urethral plate. An inner preputial flap approximately 10 mm wide is dissected on its dartos vascular pedicle and transposed ventrally. This flap can be tubularized, with the proximal end anastomosed to the spatulated native urethra and the distal end to the glans wings. B, Alternatively, one edge of the flap can be fixed with interrupted sutures to the corpora cavernosa from the proximal meatus distally into the glans. Then the flap is trimmed and the opposite edge sutured along the first to create a tube with uniform caliber. Glansplasty and skin closure are similar to that described for onlay preputial flaps.

than 30 degrees, the urethral plate is transected and additional straightening maneuvers as described earlier are performed as needed.

The corners of the dorsal prepuce are held with stay stitches and a flap 12 to 15 mm wide is outlined horizontally on its inner portion. The flap is released and its pedicle dissected to the penopubic junction. The flap can then be tubularized over a 6-Fr stent in two layers, the first using a running subepithelial 7-0 polyglactin followed by several more interrupted stitches. This tube is moved ventrally, sewn to the spatulated native urethral meatus, and then stretched distally with the suture line down against the corpora. The flap is sewn to the glans wings using interrupted subepithelial 7-0 polyglactin. Remaining glans wings are approximated using subepithelial interrupted 6-0 polyglactin.

Alternatively, the flap can be brought ventrally before its tubularization and sewn to the native urethra dorsally. Then it is stretched distally and one edge is sewn to the underlying corpora to create a pseudoplate. Excess flap skin is excised and the remaining free end is sewn to the lateral edge to complete a tube.

Results. Urethroplasty complications after proximal preputial flap repairs have been reported in 27% to 45% of onlay flaps and in 14% to 33% of tubularized flaps. Two articles suggested that complications are fewer with tubularized flaps when they are first secured to the corpora along one edge to create a pseudoplate and then fashioned into a tube.

Onlay flap repair for proximal hypospadias was reported in 126 patients with mean follow-up to 22 months. Urethroplasty complications developed in 27%, with 18 fistulas, 13 glans dehiscences, 2 strictures, 1 diverticulum, and 4 flap prolapses through the meatus (de Mattos e Silva et al, 2009). Another retrospective review described outcomes for penoscrotal onlay flaps in 75 cases with postoperative follow-up to a mean of 39 months. Complications were encountered in 45%: eight fistulas, two dehiscences, two strictures, one meatal stenosis, and five patients with recurrent VC after dorsal plication (Braga et al, 2007).

Tubularized preputial flap outcomes for penoscrotal or more proximal hypospadias were described for 27 cases with median 9 months of follow-up. Of these, 33% developed urethroplasty complications, including seven fistulas, one stricture, and one meatal stenosis (Powell et al, 2000).

Two reports described outcomes from tubed preputial flaps in which tubularization was accomplished after first suturing the flap to the corpora. In one, 12 patients with penoscrotal or scrotal hypospadias had postoperative follow-up to a mean of 24 months, during which time 2 (17%) had complications: one fistula and one meatal stenosis with diverticulum (Shukla et al, 2004). In the other, 22 boys with proximal hypospadias had a similar repair and subsequent follow-up also to an average of 24 months. There were complications in three (14%) patients: one fistula and two meatal stenoses (Aoki et al, 2008).

Byars Flaps

Byars flap refers to a two-stage operation in which the urethral plate is excised during penile straightening in the initial operation. The dorsal prepuce is split down its midline and the two parts are transferred ventrally with their dartos vascular pedicles and sutured into the defect from the meatus to the glans. At the second operation the previously transferred prepuce is tubularized (Byars, 1955).

This technique has been used following corporotomy with grafting by those who prefer a two-stage urethroplasty rather than a single-stage tubularized preputial flap. However, there are few reported outcomes. The largest, with 58 patients, only mentioned postoperative fistulas among all the possible urethroplasty complications (Retik et al, 1994). Another three studies had fewer patients. Shukla and colleagues (2004) reported results in only 10 patients with an average 43 months of follow-up, noting urethroplasty complications in 70%, including seven fistulas, three meatal stenoses, and one diverticulum. Gershbaum and colleagues (2002) had 11 patients with follow-up of "5 to 15" years, with complications in 18% (one fistula and one diverticulum), although the authors stated that 2 more patients had a "subterminal meatus or skin irregularities" that potentially increased the rate to 36%. In addition, they stated that 37% had abnormal voiding and spraying.

I (W.S.) used the operation in 9 patients with a 100% complication rate, with two fistulas, five diverticula, one stricture, and two glans dehiscences. Although fistulas and glans dehiscence are common in proximal hypospadias repair, it was diverticula, and the stricture that resulted when a less wide skin strip was tubularized to try to prevent a diverticulum, that prompted me to abandon this technique. We no longer perform Byars flaps or recommend their use.

Flaps versus Grafts

There are no trials randomizing patients with proximal hypospadias and VC greater than 30 degrees to tubularized flap versus two-stage

graft repair. Proponents of flaps state that their vascularity is assured from the pedicle, whereas that of grafts is less reliable because they must revascularize. However, Duckett once commented that fluorescein showed devascularized edges to his flaps that had to be excised, although he never published these observations in a clinical series (Duckett, unpublished comment to Hodgson, 1981).

Graft take was successful in all 43 cases reported by Ferro and colleagues (2002) using prepuce. We encountered contracture resulting in an additional procedure to partially or totally regraft in 4 of 65 (6%) patients, without a difference between prepuce and oral mucosa (Snodgrass and Bush, 2015). Our series differs from that of Ferro and colleagues in that we straightened VC in 26 (90%) of these cases using transverse corporotomies, which was done in 3 of the 4 patients with contracture. No patient has required more than one regrafting.

Urethroplasty complications that potentially indicate impaired vascularity include meatal stenosis and strictures. Tubularized flap outcomes described earlier reported meatal stenosis and/or stricture in approximately 8% (Powell et al, 2000; Shukla et al, 2004; Aoki et al, 2008), whereas 3% of two-stage grafts developed a stricture (Ferro et al, 2002). None of our patients has had either meatal stenosis or stricture.

There are also few data regarding cosmetic results. Patients we have evaluated who were operated elsewhere with flaps, an admittedly potentially biased group, most often have had glans dehiscence and a less cylindrical shape to the penis (Fig. 147-22). This glans dehiscence may be protective against diverticulum, but at the potential cost of urinary spraying.

Currently there are insufficient functional or cosmetic data to establish the best practice and determine if benefits of a two-stage repair outweigh the need for two operations.

Prepucioplasty

Prepucioplasty can be done in nearly all patients, with both distal and proximal hypospadias, whose caregivers request it (Fig. 147-23). In 1% of cases a patient has a large glans and small dorsal hood that prevent prepucioplasty. When prepucioplasty is done for proximal hypospadias in which urethral plate transection is needed for VC straightening, two-stage repair uses an oral labial mucosa graft.

Indications. Foreskin reconstruction is indicated in any primary hypospadias repair when caregivers prefer it to circumcision. We simply ask if newborn circumcision was anticipated and, if not, offer prepucioplasty.

Surgical Technique. Stay sutures are placed into the corners of the dorsal prepuce (see Fig. 147-23A). Initial incision extends from these points, lateral to the glans, and then to a point approximately

Figure 147-22. Appearance after flap and graft repair for proximal hypospadias. **A**, Tubularized flap repair with a pyramidal shape of the penis. **B**, The same patient, who appears to have a slit meatus, is noted instead to have glans dehiscence with a coronal meatus. **C**, Cylindrical penile shape and slit meatus with well-healed glansplasty after two-stage preputial graft repair.

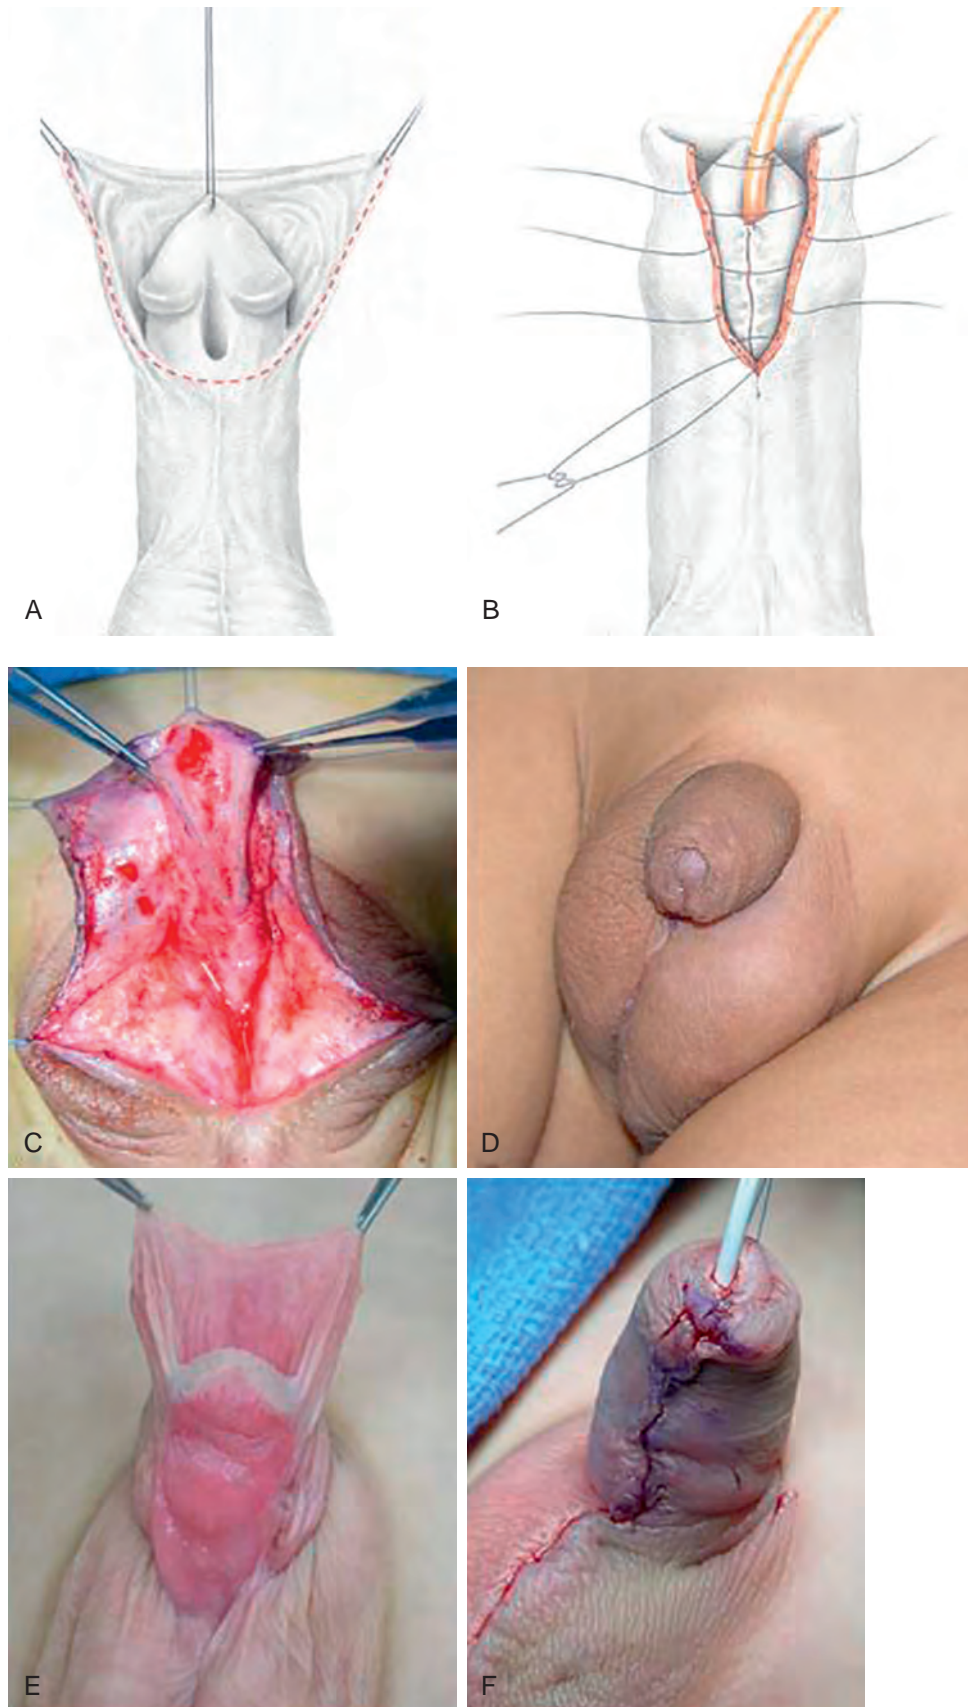

Figure 147-23. Prepuceplasty. A, V-shaped incision from the corners of the dorsal prepuce extending ventrally to below the meatus. B, Skin closure. C and D, Proximal tubularized incised plate urethroplasty with prepuceplasty. Note the excellent ventral exposure gained without degloving the penis. E and F, Two-stage proximal repair using oral mucosa graft.

2 mm below the meatus. The penis is not degloved, and ventrally dissection is done immediately under the skin to preserve dartos for a barrier flap until normal tissues are encountered, generally near the penoscrotal junction.

Urethroplasty and glansplasty are done as already described for distal or proximal TIP or two-stage graft repairs.

After glansplasty the foreskin stays are pulled down below the glans and the inner prepuce is approximated using subepithelial 7-0 polyglactin. Then the stays are pulled distal to the glans. These corners are approximated together also using subepithelial 7-0 polyglactin. Previously we adjusted the position of this initial stitch to allow the foreskin to readily retract back and forth over the glans. However, this sometimes leaves the prepuce visibly deficient ventrally, and so today we suture it to achieve the best appearance and are not concerned about its retractability, given that normal boys the same age as those undergoing hypospadias repair often have similarly nonretractable foreskin. The remainder of the incision is closed using interrupted 7-0 polyglactin. Caregivers are instructed not to retract the foreskin.

Results. Urethroplasty and skin complications are the same after distal or proximal TIP or two-stage graft repairs, whether circumcision or prepucioplasty is done.

Suoub and coworkers (2008) compared 25 distal TIP repairs with prepucioplasty to an age- and time-matched cohort of 49 distal TIP repairs with circumcision, reporting no difference in either urethroplasty or skin complications. The only urethroplasty complications were fistulas, occurring in 12% and 8%, respectively. One patient with "recalcitrant" phimosis had secondary circumcision after prepucioplasty versus two with "redundant skin" after circumcision who had circumcision revision (Suoub et al, 2008).

Snodgrass and colleagues (2013) also reported a case-cohort study of 428 consecutive distal TIP urethroplasties of which 85 had prepucioplasty. There were no intraoperative conversions to circumcision. Urethroplasty complications developed in 8% after prepucioplasty and 9% after circumcision. Two percent of each group had subsequent skin revision, which included one circumcision for BXO 5 years later and one excision of an unsightly dorsal whorl without circumcision following prepucioplasty.

Snodgrass and Bush (2011) did prepucioplasty during proximal TIP urethroplasty in 21% of cases (all who requested it), with none having postoperative urethroplasty or skin complications. Prepucioplasty was also done in 25% of those undergoing two-stage graft repair (all who requested it), with none having recurrent curvature or urethroplasty or skin complications (unpublished data).

Because prepucioplasty does not increase either urethroplasty or skin complications, the choice between it and circumcision should be mentioned to all caregivers, allowing them to determine the final cosmetic appearance.

Scrotoplasty

In the last edition of this textbook "major" scrotoplasty using rotational skin flaps to correct penoscrotal transposition was illustrated. Today we no longer perform this maneuver, having found that we can correct transposition with ventral penoscrotal incisions leaving no visible scars. Instead, shaft skin adjoining the scrotum is incised ventrally to 3 and 9 o'clock, and then the scrotum is rotated down to create a new penoscrotal junction and sutured to the corpora on either side of the neourethra with 5-0 polydioxanone as shown in Figure 147-16.

POSTOPERATIVE MANAGEMENT

Urinary Diversion

Several studies reported that distal TIP urethroplasty in pre-toilet-trained boys can be done without diversion, expecting less than 5% to need catheterization early postoperatively and no increase in urethroplasty complications.

One trial of toilet-trained boys found greater dysuria, retention, and extravasation in those not catheterized, resulting in

catheter placement in 40% of those not randomized to diversion. Urethroplasty complications were not impacted by whether or not diversion was used.

There are no data indicating benefit of suprapubic diversion in addition to or as a substitute for urethral catheters.

Three studies reported results for midshaft to distal TIP urethroplasty without urinary diversion in non-toilet-trained patients:

- Almodhen and associates (2008) reported on 32 consecutive non-toilet-trained boys (mean age 18 months) who had TIP urethroplasty for distal to midshaft and proximal shaft ($n = 6$) hypospadias without a catheter. One (distal vs. proximal not stated) developed urinary extravasation on the second postoperative day that was treated with catheterization. One patient (3%) had a urethroplasty complication (meatal stenosis) during follow-up of 9 ± 6 months.
- Samuel and colleagues (2002) reported on 170 consecutive patients (mean age 19 months) who had distal TIP repair without diversion. None had urinary retention or needed catheterization. Urethroplasty complications occurred in 7% during follow-up to a mean of 3 years.
- Leclair and associates (2004) reported on 162 consecutive patients (mean age 16 months) with distal or midshaft ($n = 6$) TIP repair without diversion. Catheterization was needed for urinary retention in 4 patients (2.5%), 2 within hours of surgery and 2 at 1 week postoperatively, without subsequent complications. Urethroplasty complications occurred in 8%, both fistulas and meatal stenoses.

An RCT by El-Sherbiny (2003) compared outcomes in 64 toilet-trained boys (median age 6 years) to distal TIP urethroplasty with versus without catheterization, decided at the end of the operation. Urethroplasty complications were similar in both groups (3 of 35 stented vs. 6 of 29 not catheterized, $P = .3$). However, dysuria (14% vs. 45%), retention (0 vs. 24%), and extravasation (0 vs. 17%) occurred significantly more often in those not diverted. Of the 29 patients not catheterized, 12 (41%) were catheterized within 3 days of operation.

We have used urinary diversion to avoid need for postoperative catheterization in the minority of pre-toilet-trained patients who otherwise will develop retention or extravasation. A 6-Fr bladder stent is used for all repairs in prepubertal boys, versus a 12- to 14-Fr catheter after puberty. For patients who are operated before toilet training, the catheter drains into a single diaper. We never use suprapubic tubes in either primary or reoperative hypospadias repair.

Given that most infants undergoing distal repairs in these studies did not require diversion, we recently began performing distal TIP urethroplasty without a stent, which obviates need for postoperative antibiotics and facilitates early, normal bathing resumed at 48 hours after surgery.

Bandages

Two trials reported no differences in urethroplasty outcomes whether or not bandages were used.

To our knowledge only two studies consider the possible impact of postoperative bandages on urethroplasty outcomes:

- Van Savage and colleagues (2000) randomized 100 patients to a transparent waterproof adhesive bandage around the penis removed by parents 2 days after surgery versus no bandage. Two were excluded for bleeding at the end of the operation. There were no differences in urethroplasty complications at mean follow-up of 1 year, but telephone calls were significantly more frequent from parents of those without a bandage than from parents of those with a bandage (0.8 vs. 0.3 calls/patient). The authors did not state if these reported calls referred to wound questions versus other concerns.
- McLorie and associates (2001) allocated 120 patients at the end of repair to a transparent biomembrane adhesive film versus compressive wrap versus no bandage with polymyxin B and bacitracin zinc in white petrolatum applied at each diaper change for 7 days. Three patients were withdrawn for bleeding

Figure 147-24. Postoperative bandage.

requiring a compressive dressing. Bandages were removed at 3 or more days and white petrolatum was then applied for another 7 days. There were no differences among groups with regard to urethroplasty complications.

If bandages do not impact urethroplasty outcomes, then various wraps that may be painful to remove can be avoided. We use a Tegaderm (3M, St. Paul, MN) adhesive around the penis and a second holding a gauze over the wound, both of which fall off spontaneously at home (Fig. 147-24).

Medications

Antibiotics

One trial reported that postoperative oral cephalexin reduced the incidence of febrile UTI.

The only trial regarding postoperative antibiotics after hypospadias repair included 101 patients undergoing TIP urethroplasty who all received intraoperative intravenous cefonicid and then were randomized to postoperative oral cephalexin for 8 days during urinary diversion versus no antibiotic. Urethroplasty outcomes were the same but febrile UTI occurred in 3 of 52 antibiotic-treated versus 12 of 49 untreated patients ($P < .05$) (Meir and Livne, 2004).

We do not use intraoperative antibiotics during hypospadias repair except for those patients having oral mucosa harvest, to whom intravenous cefazolin is given. Postoperatively trimethoprim-sulfamethoxazole is given during urinary diversion.

Analgesics and Antispasmodics

We recommend oral ibuprofen 4 times daily alternating with acetaminophen for infants to children approximately 2 years of age. Older children are provided hydrocodone with acetaminophen to use between ibuprofen doses as needed.

Oxybutynin 0.2 g/kg per dose up to 5 mg is given twice daily, or as a single extended-release tablet, to patients 3 years of age or older.

OUTCOMES ASSESSMENT

Hypospadias repair is much more than simply urethroplasty, and outcome assessment includes genital appearance as well as penile functions of urination, erection, and ejaculation. In children most emphasis has been on urethroplasty complications, with less on cosmetic results. Available data regarding sexual functions in adults

are reviewed in the later section on [Adult Outcomes after Prepubertal Repair](#).

Duration of Follow-Up

Eighty percent of urethroplasty complications are diagnosed within 1 year after surgery, with indefinite follow-up needed in 14 patients for each complication subsequently encountered.

Snodgrass and colleagues (2014a) reported the time at which any urethroplasty complication was diagnosed after 887 primary and reoperative TIP repairs. There were a total of 125 complications—54 fistulas, 59 glans dehiscences, 9 meatal stenoses or neourethral strictures, and 3 diverticula—of which 64% were diagnosed at the first postoperative visit and 80% within the first postoperative year. Median time to encounter fistulas, meatal stenoses and strictures, and diverticula was 6 months, whereas glans dehiscence was diagnosed at a median of 2 months. After 1 year we calculated that 14 patients would require indefinite follow-up for each additional complication eventually diagnosed (Snodgrass et al, 2014a).

Continuous longitudinal follow-up to puberty has never been reported for patients undergoing prepubertal hypospadias repair. Several retrospective reviews evaluating the time to diagnosis of urethroplasty complications reported late complications (after 1 year) in those patients who returned because of their complication. Wood and associates (2008) studied fistulas and found that 70% were diagnosed by 1 year, but the tally did not reach 90% and 99% until follow-up at 8 and 20 years. Spinoit and colleagues (2013) reported 24% of reoperations for urethroplasty complications or unsatisfactory appearance were done at more than 2 years postoperatively, but that after 3 years 15 boys would need assessment for each additional complication found.

Clearly more complications are potentially found as duration of follow-up increases. However, many boys who will never have a complication have to be reviewed indefinitely for each additional one diagnosed after 1 year. We recommend office assessment at 6 weeks and then 6 months later (8 months postoperatively) after distal TIP urethroplasty and advise caregivers at the last visit that a complication may become apparent at a future date. After proximal repairs we request annual follow-up with the academic goal of determining functional outcomes pre- and postpuberty, given the greater degree of VC and the longer urethroplasty with proximal hypospadias.

Calibration

The minimum caliber of the normal urethra in boys varies in published reports. One study found that 14% of boys less than 3 years of age were less than 8 French.

Calibration of the neourethra is an objective means to establish that there is no anatomic obstruction after urethroplasty. We routinely calibrate pre-toilet-trained patients with a 10-Fr sound at the 8-month postoperative visit, but the very low prevalence of obstruction supports limiting calibration to infants with questionable obstructive voiding and/or a small-appearing meatus.

Normal meatal size was determined by Allen and colleagues (1972) in 100 consecutive full-term newborns using bougies à boule or olive-tipped catheters on day 2 of life. The mean and median was 8 French, with half the patients less than 8 French to as small as 4 French in 10%. Another study also used bougies à boule in 200 referred patients, reporting that 14% were less than 8 French to age 3 years (Litvak et al, 1976).

Uroflowmetry

No study provides flow rates in patients compared to age-matched controls, and outcomes based on nomograms may vary depending on the nomogram used.

Approximately 25% of patients after TIP repair or onlay or tubularized preputial flap repair have Qmax less than 2 standard deviations below normal based on varying nomograms, yet have

no symptoms. The significance of this finding in asymptomatic patients is unknown.

Following Tubularized Incised Plate Urethroplasty

Andersson and colleagues (2011) reported flow rates in 37 asymptomatic boys from a total of 126 distal and proximal TIP repairs. At 1 year the mean Qmax was 13.6 mL/sec (range 6 to 28), with half below the 5th percentile on the Miskolc nomogram. At an average of 6 years later the mean Qmax was 19 mL/sec and 32% were below the 5th percentile, a significant improvement. The authors stated that fewer patients would have been categorized as below the 5th percentile had the Toguri nomogram been used (Andersson et al, 2011).

Snodgrass (1999) reported uroflowmetry in 17 of the first 50 toilet-trained boys following TIP urethroplasty, determined at a mean of 45 months (range 6 months to 7 years) postoperatively. All peak flows were above the 5th percentile based on the nomogram used by Jayanthi and colleagues (1995) (which was not reported in the article).

Considering Qmax less than 2 standard deviations from normal a possible indication of obstruction, a review by Gonzalez and Ludwikowski (2011) of reported TIP uroflows found that 36 of 140 (26%) asymptomatic patients in three articles using different nomograms met that criterion.

We hypothesize that the Qmax changes little after initial healing but that at puberty the increased urethral diameter should increase the flow rate. Currently we have limited data in patients before and after pubertal development. In two the Qmax improved from 7 to 19 mL/sec and 13 to 20 mL/sec at Tanner stage 4. Three others have no change in Qmax at Tanner stage 2.

Following Preputial Flaps

Jayanthi and colleagues (1995), in a review of uroflows in 51 toilet-trained boys following either onlay or tubularized preputial flaps, reported that 27% had Qmax below the 5th percentile of an institutional nomogram.

Patel and coworkers (2004) obtained uroflowmetry a mean of 14 years after proximal repair in infancy (mean age 17 months) and reported a mean Qmax of 17 mL/sec without differences between onlay and tubularized flaps.

Cosmetic Results

Two studies used standardized photographs to compare TIP versus flap cosmetic outcomes, both reporting higher scores for TIP repairs. A questionnaire study compared TIP patients to controls after circumcision and found similar ratings by caregivers 6 weeks after surgery.

Objective assessment of genital appearance after hypospadias surgery is not commonly reported. Two studies used photography scored by blinded reviewers to compare TIP to Mathieu (appendix) or onlay flaps. Both reported TIP scores significantly higher (Ververidis et al, 2005; Scarpa et al, 2009).

Snodgrass and colleagues (2008) used a nonvalidated questionnaire answered by caregivers before physician examination 6 weeks after distal or proximal TIP urethroplasty versus controls following circumcision. There were no differences in Likert scale scores regarding overall appearance or the specific appearance of the meatus or penile skin.

Hayashi and associates (2007) compared photographs after standard onlay to photographs after a modified V-shaped incision ventrally to create a more vertical meatus shape. Overall improvement was reported, with 8 of 25 standard versus 12 of 18 modified repairs achieving a slit meatus ($P = .03$). A V-shaped incision was effective in all 4 patients with a deeply grooved and in 6 of 9 with a moderately grooved plate, but in only 2 of 5 with a flat configuration.

There are no other studies concerning aesthetic appearance of the penis after flap repairs. Although the V-shaped incision proposed by Hayashi and associates (2007) did result in more patients with a slit meatus, the patients most likely to have a rounded

appearance with flaps are those with a flat plate, and V-shaped incision was effective in fewer than 50% of those.

COMPLICATIONS

Risk Factors

Risk factors for urethroplasty complications include proximal meatus, reoperation, and glans width less than 14 mm. Studies in which patients did not routinely have barrier flaps over the neourethra have found that this is also a risk factor for complications (fistulas).

Bush and colleagues (2012) used multivariate analysis to evaluate potential risk factors for hypospadias urethroplasty complications among 669 consecutive prepubertal TIP repairs, using prospectively recorded data. These included patient age, meatal location, reoperation, glansplasty suture type (chromic vs. polyglactin), and surgeon learning curve (defined as the first 50 cases). Of these, the only independent factors were reoperation (odds ratio [OR] 3.07, 95% confidence interval [CI] 1.54 to 6.13) and proximal meatus (OR 1.79, 95% CI 1.33 to 2.40).

Bush and colleagues (2013) subsequently analyzed 391 patients with glans measurements for patient age, meatal location, reoperation, and glans width (in millimeters). Meatal location and reoperation remained independent factors, but so was glans width less than 14 mm (OR 3.7, 95% CI 1.6 to 8.5), with each 1-mm increase in glans size decreasing complications.

Two other reports used multivariate analysis of retrospectively collected data after TIP urethroplasty. Eassa and associates (2011) evaluated 391 patients operated by five surgeons, analyzing for age, meatal location, reoperation, surgeon, urethroplasty sutures (polyglactin vs. polydioxanone) and methods (interrupted vs. continuous), a flap over the neourethra, and urinary diversion. Only proximal meatus location (relative risk [RR] 2.81, 95% CI 1.42 to 5.52), age greater than 4 years (RR 3.25, 95% CI 1.44 to 7.35), and no barrier flap (RR 6.23, 95% CI 1.87 to 20.77) were risk factors. Sarhan and coworkers (2009) evaluated 500 patients operated by five surgeons, analyzing for age, meatal location, reoperation, urethroplasty suturing method (interrupted vs. continuous), neourethral coverage, urinary diversion, and learning curve (defined as the first 100 cases). Independent risk factors were proximal meatus, no barrier layer, and learning curve.

We cannot model for barrier layers or urinary diversion because both are used systematically. As discussed earlier, we did not find age at repair to be an independent risk factor for urethroplasty complications.

Modifying Risk Factors

Meatal Location

Only 10% of primary cases present with a meatus on the proximal shaft to the perineum. Case logs reported to the American Board of Urology by U.S. pediatric urologists requesting a certificate of added qualification indicated the average number of proximal repairs done annually was two (Kogan and Feustel, 2011). Given that proximal meatus location is a consistent risk factor for urethroplasty complications, we recommend that centers designate a single surgeon to perform these cases to increase his or her expertise.

Reoperation

Initial failure increases risk for additional failure. We recommend that surgeons review their personal outcomes and consider changes in procedure and/or technique to reduce complications, as we discussed earlier in the chapter. The Results section under Proximal Hypospadias Repair details technical modifications we have made that significantly reduced urethroplasty complications after proximal TIP urethroplasty.

Academic surgeons must ensure good outcomes for the patient when allowing trainees to actively participate in key steps of the surgery, especially urethroplasty and glansplasty.

A survey by [DeLair and coworkers \(2008\)](#) of mostly senior urology residents having completed more than 75% of their training found that few had performed glans wings dissection or urethroplasty. Fellows in our program also observe these key steps until faculty conclude that their skills are satisfactory, and they rarely perform more than 50% of any given repair. Bush compared distal TIP outcomes of our former fellows in consecutive cases done over a 2-year period beginning 3 or fewer years after training to those of Snodgrass during the same time frame. There were no significant differences in urethroplasty complications among the former fellows or between them and Snodgrass (Bush et al, unpublished).

We also recommend that reoperations in major centers be done by a single surgeon.

Glans Size

As discussed in the earlier section on [Preoperative Androgen Stimulation](#), preoperative androgens are known to increase glans width. We analyzed urethroplasty complications in patients who received adjuvant testosterone injections versus those with glans 14 mm or greater who did not. Mean glans width before stimulation was 12 mm, increasing to a mean of 16.5 mm with testosterone injections. Untreated patients had a mean glans width of 15.4 mm. Urethroplasty complications occurred in 34% with versus 11% without adjuvant androgens ($P < .0001$). Testosterone was found to be an independent risk factor for complications in this analysis (OR 3.1, 95% CI 1.2 to 8.1). Accordingly, we have stopped preoperative testosterone stimulation ([Bush et al, 2013](#)). Now we use the extended glans wings dissection described earlier for patients with glans width less than 14 mm. Although we do not yet have outcomes data, this technique has a reported glans dehiscence rate of 1 in 150 cases despite an average glans width of 12 mm (Tanakazi and Yoshino, personal communication).

Fistulas

Prevention. Subepithelial suturing and dartos flap coverage over the neourethra are thought to reduce fistulas. Two-layer subepithelial urethroplasty with tunica vaginalis flap coverage was reported to significantly reduce fistulas when compared to single-layer epithelial closure and dartos flap coverage in proximal TIP urethroplasty.

Subepithelial urethroplasty was superior in a retrospective analysis of [Mathieu operations by Ullman and associates \(1997\)](#). They compared single-layer continuous urethroplasty done in 36 initial patients with 6-0 polyglactin sutured through the epithelium to that done in 61 later boys using 7-0 polydioxanone subepithelial stitching. With follow-up of 6 to 12 months, fistulas occurred in 6 of the 36 patients with epithelial stitching (17%) versus 3 of the 60 patients with subepithelial stitching (5%) ($P < .01$).

Use of a barrier flap or not was the subject of a trial by [Savanelli and coworkers \(2007\)](#) that randomized 130 patients undergoing distal TIP repair. Three surgeons performed the operations using the same urethroplasty technique and suture. During median follow-up of 24 months, fistulas occurred more often in those without a dartos flap: 15 of 65 (23%) versus 5 of 65 (8%) ($P = .03$). Meatal stenosis and glans dehiscence were similar in both groups (4% and 5%, respectively).

[Bakan and Yildiz \(2007\)](#) compared a single-layer dartos flap to a two-layer flap. The single-layer dorsal dartos flap was used in 29 consecutive patients, followed by a two-layer flap in the next 45. More boys in the second group had midshaft to proximal hypospadias or reoperations, but fistulas only occurred in the single-layer patients (4 [14%] vs. 0, $P = .02$).

As mentioned, I (W.S.) made technical modifications to proximal TIP urethroplasty that reduced fistulas from an initial 5 of 15 (33%) to 2 of 20 (10%) to 0 of 24 consecutive patients (see [Results](#) section under [Proximal Hypospadias Repair](#)). The first 15 patients had single-layer epithelial suturing of the neourethra using 7-0 chromic catgut. The next 20 had two-layer subepithelial urethroplasty using interrupted 7-0 polyglactin and continuous 7-0 polydioxanone. Spongioplasty after urethral tubularization was added to the second group. In the last 24 cases a tunica vaginalis flap, rather than dartos, covered the repair ([Snodgrass and Bush, 2011](#)).

Surgical Repair. Repair includes assessment for distal obstruction, excision of the fistula tract with closure of the urethral opening, and flap coverage over the defect.

The neourethra is calibrated distally to determine if it is 8 French or greater. Then fluid is injected into the neourethra to confirm the fistula site(s). We make a median raphe incision that encircles the fistula and continues proximally ([Fig. 147-25](#)). The tract is excised and the urethral hole is closed in one layer using subepithelial

Figure 147-25. Fistula repair. A, Coronal fistula with good distal glans wings approximation. An incision is made around the fistula that continues in the median raphe distally to gain access to ventral dartos for a coverage flap and to revise the redundant shaft skin. B, Exposure showing the glans can be elevated away from the fistula to facilitate fistula closure and coverage with a ventral dartos flap without need for reoperative glansplasty. C, Coronal fistula with a band of skin holding the glans wings together. This requires tubularized incised plate reoperation rather than simple fistula closure.

interrupted 7-0 polyglactin. Repeat fluid injection confirms watertight closure. A ventral dartos flap is raised and used to cover the repair. We do not use urinary diversion.

Repair of coronal fistulas depends on the extent of glans fusion. When the glans is well formed the fistula can be closed by elevating the glans without reoperative hypospadias repair. When the glans wings are separated and held by only a band of skin (see Fig. 147-25C), reoperation is done as described in the later section on [Glans Dehiscence](#).

Results. Three series reported failure in from 6% to 29% of cases, with no differences whether or not urinary diversion was used.

A retrospective review by [Shankar and colleagues \(2002\)](#) had 113 cases of fistulas, of which 7% also had distal obstruction. Subepithelial closure and flap coverage were done, with urinary diversion for 1 week. A total of 29% of patients developed recurrent fistulas, more likely in those with initial fistulas greater than 2 mm versus those smaller. [Waterman and colleagues \(2002\)](#) used diversion in 54 of 100 fistula closures with “larger” defects but found no difference in recurrences, which also developed in 29% of patients, based on stenting. A third review by [Santangelo and associates \(2003\)](#) considered 69 “simple” and 25 “complex” fistulas (larger, and/or with distal obstruction or a diverticulum) that were corrected by closure and flap coverage generally without a stent or by reoperation/meatotomy plus fistula repair in which stents were used, respectively. Both groups had similar recurrences, which overall developed in 6%.

Our recurrence rate for fistula closure as described earlier, excluding those patients with hypospadias reoperation, is 8% (Snodgrass, unpublished data).

Glans Dehiscence

Glans dehiscence occurs more often following proximal and reoperative surgeries, and in patients with glans width less than 14 mm.

We define glans dehiscence as complete separation of the glans wings, with or without a band of skin bridging the gap between the wings (Fig. 147-26). In addition to abnormal appearance, glans dehiscence creates a functional impairment with a deviated and/or spraying stream. Partial dehiscence results in a larger meatus, but with glans wings fusion between the meatus and corona. We do not repair these unless there is a spraying stream, which is the same decision-making criterion we use in patients presenting with glanular hypospadias to determine who will have repair.

[Snodgrass and colleagues \(2011\)](#) used multivariate analysis in 641 consecutive patients following distal, proximal, and reoperative TIP urethroplasty (most of which was for prior dehiscence), and found glans dehiscence in 5%. Risk was nearly four times greater in proximal repairs and almost five times greater in reoperations.

This is our most frequent hypospadias complication, yet it is not often reported in other series. Our glansplasty technique may be inferior and/or this complication is underreported. Based on patients referred to us after failed surgery elsewhere, we believe the complication is more common than realized. However, after observing glansplasty in glans less than 14 mm in Japan, we also realized a potentially better glansplasty involving extended glans wings dissection could be done to reduce this occurrence, as described in this chapter.

Prevention

We first changed sutures from chromic to polyglactin after recognizing glans dehiscence, but the subsequent analysis mentioned earlier showed no difference based on these sutures. Next we used preoperative testosterone to increase glans size to 15 mm or greater, but similarly found no decrease in this complication in treated patients. Currently we dissect the glans wings from the corpora completely to 3 and 9 o'clock in all patients, which is a more systematic dissection than previously. Then in patients with glans width less than 14 mm, prior dehiscence, and/or subjective tight approximation after standard dissection, we further release the wings superiorly for about 4 mm as shown in [Figure 147-11](#).

Surgical Repair

Reoperative TIP or inlay grafting is used to repair glans dehiscence, as described in the later section on [Hypospadias Reoperations](#).

Results

[Villanueva and colleagues \(2012\)](#) reported outcomes for reoperations to correct glans dehiscence before adopting the extended glans wings dissection currently used. Instead, the glansplasty was basically repeated using dissection of the glans wings to approximately 3 and 9 o'clock and then approximation with three interrupted subepithelial 6-0 polyglactin sutures. Recurrent dehiscence developed in 18 of 111 patients (16%). Of these 18, 10 had a third similar glansplasty, but 5 of 8 (63%) with follow-up dehisced again. Today, if reoperative glansplasty with extended glans wings

Figure 147-26. Glans dehiscence. A, Complete separation of the glans wings with a subcoronal meatus. B, The glans wings are separated, but a skin bridge between them gives the division of a glanular meatus. This patient had a spraying urinary stream corrected by reoperative glansplasty.

dissection fails, we advise no further surgery until the patient reaches late puberty.

Meatal Stenosis

There is no agreed-upon definition for meatal stenosis. We diagnose stenosis when the neomeatus is less than 8 French in a boy with voiding symptoms. Our results suggest that most meatal stenosis is iatrogenic. There is no report of outcomes for meatotomy after hypospadias repair.

We have evaluated for second opinions patients with a small-appearing meatus who are asymptomatic following hypospadias repair and have been recommended for meatotomy, yet a 10-Fr sound passes easily. These boys do not need intervention. There is no accepted definition of meatal stenosis, which we define as meatal size less than 8 French after repair in a symptomatic patient (i.e., one with dysuria, stranguria, retention, and/or febrile UTI). A standardized literature review by [Wilkinson and colleagues \(2012\)](#) included 15 case series describing distal TIP outcomes in 1872 patients. The authors noted that the diagnosis of meatal stenosis was not standardized, and so likely varied among these publications, but was reported in 3% of patients.

[Snodgrass and coworkers \(2010\)](#) reported outcomes in 426 consecutive patients with distal hypospadias, all of whom had TIP urethroplasty. Of these, 263 (62%) had calibration with none having meatal size less than 8 French. One patient developed secondary meatal stenosis from BXO 6 years following surgery.

Prevention

Given our outcomes, meatal stenosis after TIP urethroplasty appears to be avoidable. We have emphasized technical factors to reduce risk, including incision limited to the urethral plate, not extending into the glans distally, and continuing to near the underlying corpora; tubularization of the plate that begins at least 3 mm from its distal end, creating an oval opening; and independent glans wings approximation without suturing to the neourethra.

Surgical Repair

We incise the neomeatus dorsally to enlarge it without re-creating the hypospadias defect. Meatal stenosis that nearly obliterates the opening, or is the result of BXO, requires reoperative hypospadias repair as described in the later section on [Hypospadias Reoperations](#).

Results

We found no articles defining meatal stenosis or reporting outcomes from meatotomy after hypospadias repair.

Neourethral Stricture

Strictures of the neourethra are unusual following hypospadias repair using any of the techniques described in this chapter. A review of the outcomes tables that accompanied the hypospadias chapter in the prior edition of this textbook shows few mentions of stricture, the highest prevalence being 9% in both a report of tubularized preputial flaps ([Ghali, 1999](#)) and a report of Koyanagi flaps ([Koyanagi et al, 1994](#)).

We encountered no strictures in our series of 426 distal TIP repairs ([Snodgrass et al, 2010](#)). However, strictures did occur in 5 of 29 (17%) proximal TIP repairs in which the urethral plate and native urethra were dissected from the corpora to preserve the plate while straightening VC. All these patients presented 6 weeks to 1.5 years postoperatively with symptoms of retention and/or febrile UTI. Another 47 proximal TIP repairs without this maneuver had no strictures. Accordingly, we have discontinued this maneuver and not described it in this chapter.

However, a retrospective review by [Bhat \(2007\)](#) of 32 patients with urethral plate and native urethra elevation from the corpora

followed by tubularization done with ($n = 20$) or without TIP incision reported no strictures during an average 24 months of follow-up. We cannot explain the difference in these observations.

Treatment

Options include direct vision internal urethrotomy (DVIU), which is effective for strictures less than 1 cm following urethral plate tubularizations and onlay preputial flaps, but not tubularized flaps or grafts. Repeat DVIUs for recurrent strictures less than 1 cm all failed.

Mobilization of the urethra with stricture excision has not been reported for strictures after hypospadias repair, to our knowledge.

Inlay or two-stage oral mucosa grafting, described in the later section on [Hypospadias Reoperations](#), are both options depending on the etiology of the stricture (focal ischemia versus BXO, respectively), the extent to which the neourethra is obliterated, and the presence of secondary VC when there is neourethral contracture.

Results

A single DVIU was successful in approximately 66% of patients with strictures less than 1 cm after urethral plate tubularizations or onlay flaps. Repeat DVIUs all failed. Dorsal inlay grafting was used in one series with success in 94% at 2-year follow-up.

DVIU for strictures less than 1 cm achieved relief of voiding symptoms and Qmax greater than 12 mL/sec in 0 of 32 tubularized grafts and 2 of 18 (11%) tubularized flaps, versus 8 of 11 (72%) onlay flaps and 7 of 11 (63%) urethral plate tubularizations (each $P < .05$). Patients were randomized to post-DVIU dilations or not with no difference in outcomes. Repeat DVIU for 12 of 32 recurrent strictures still less than 1 cm were all failures. Follow-up was a minimum of 2 years ([Husmann and Rathbun, 2006](#)).

Dorsal inlay graft was used in 37 strictures after a mean of two hypospadias surgeries in a series of patients with mean age 12 years. During follow-up for a mean of 2 years, recurrent strictures were diagnosed in only 3 patients (6%) ([Ye et al, 2008](#)).

Diverticulum

Five of nine patients undergoing Byars flap repair for proximal hypospadias by me (W.S.) developed diverticula. None had distal obstruction and the strip that was tubularized was approximately the width of the open glans. I concluded that this ballooning resulted from the relatively fixed resistance of the glans and/or turbulent flow from poor fixation of the flap to the corpora, causing the preputial skin to stretch ([Fig. 147-27](#)).

Figure 147-27. Byars flap.

Dartos under the flap prevents adherence of the epithelium to the underlying corpora, potentially increasing risk for turbulent flow and diverticulum formation.

A retrospective review of onlay versus tubularized preputial flap repairs by [Wiener and colleagues \(1997\)](#) found that 12% of those tubularized developed diverticulum during follow-up to a mean of 20 months, which might suggest that tubed flaps have greater risk than onlays for this complication. However, [Vallasciani and associates \(2013\)](#) reported 7% diverticula after both onlay and tubularized preputial flap repairs during mean follow-up of 7 years; none had distal obstruction. Therefore, diverticulum can develop after either single- or two-stage tubularized flaps or onlay preputial flaps despite absence of distal obstruction. Diverticula are much less often encountered after urethral plate or graft tubularizations.

Surgical Repair

Calibration is done to detect associated distal stenosis. Then the diverticulum is exposed by a ventral median raphe incision and opened. A dorsal strip of sufficient width is outlined and the excessive tissue to either side is de-epithelialized. The neourethra is sutured in two layers over a catheter to restore a normal caliber and the redundant and de-epithelialized flaps are closed with vest-over-pants suture to cover the repair.

Results

All 5 patients reported by [Vallasciani and associates \(2013\)](#) were successfully repaired without recurrent diverticulum during follow-up for an average of 9 years.

Balanitis Xerotica Obliterans

BXO can present both preoperatively and following hypospadias repair. It is clinically diagnosed by the characteristic white discoloration of the involved tissues ([Fig. 147-28](#)). BXO at the urethral meatus can both cause stenosis and extend into and along the urethra, inducing stricture.

Medical treatment using a topical steroid or tacrolimus has been reported. A double-blind RCT compared 0.05% mometasone furoate to placebo applied daily for 5 weeks for BXO phimosis. Although steroid therapy significantly improved foreskin retraction, histologic findings of BXO persisted ([Kiss et al, 2001](#)). Therefore best treatment is complete excision of all involved tissues with oral mucosa graft urethral replacement.

We have anecdotal experience with 2 patients with recurrent BXO after prior excision and oral mucosa grafting. In both the

condition recurred at the new junction of the glans to the neourethra, in one 9 years later. Both have been managed with periodic topical therapy to control symptoms, given concerns that BXO could recur again at the skin margin if further excision is done.

Surgical Repair

BXO is surgically excised. When it occurs at the meatus or within the urethra, all grossly involved tissues are removed and replaced with oral mucosa in a two-stage graft urethroplasty described in the later section on [Two-Stage Oral Mucosa Graft](#). Use of either genital or nongenital skin rather than oral mucosa is associated with BXO recurrence.

Results

[Bracka \(2011\)](#) changed from skin grafts to oral mucosa to treat BXO after observing initially good results with subsequent failure when BXO recurred. However, he did not present data indicating the percentage of recurrences or the time frame in which they occurred.

To our knowledge there are no credible reports of BXO recurrence within oral mucosa.

HYPOSPADIAS REOPERATIONS

Although fistulas are the most common complication following hypospadias repair, glans dehiscence is the most common indication for reoperative urethroplasty. Regardless of the problem requiring reoperation, decision making is systematic (see [Fig. 147-7](#)). If the urethral plate remains and is not grossly scarred, TIP urethroplasty is the first option. When the plate has been excised but a skin strip without gross scarring remains, then inlay grafting is the preferred repair. When the urethral plate or skin substitute is grossly scarred or there is VC greater than 30 degrees, neourethral hair, BXO, or stricture that nearly obliterates the lumen, two-stage oral mucosa grafting is done.

Although skin flap reoperations are an option when there is sufficient skin for urethroplasty without compromising penile shaft covering, we do not often encounter such patients and do not use flaps.

In addition, when a Mathieu or onlay flap has been done in a patient requiring reoperation, we remove the flap and perform TIP urethroplasty, both to securely approximate the glans wings and to avoid a potential diverticulum once the glans is well closed.

When there are indications for a two-stage graft repair, we completely excise the unhealthy neourethra to native urethra so that the

Figure 147-28. Balanitis xerotica obliterans (BXO). A, BXO causing secondary phimosis after prepuceplasty. B, Perimeatal BXO causing meatal stenosis. C, Wound dehiscence subsequently developed extensive BXO around the meatus and surrounding shaft skin.

final neourethra has uniform composition to reduce concern for contracture at tissue junctions or a diverticulum from tubularizing tissues of varying elasticity.

Tubularized Incised Plate Urethroplasty

Indications

Reoperative TIP urethroplasty is an option when the urethral plate remains after prior surgery and lacks gross scarring. In our series of 133 consecutive reoperations (Snodgrass et al, 2009), 69 patients (52%) with a mean of 1.1 failed repairs (range 1 to 3) met those criteria.

Surgical Technique

A ventral Y incision is made, re-creating glans wings along their visible junction to the urethral plate and continuing in the median raphe to near the penoscrotal junction (Fig. 147-29). The glans wings are first dissected laterally along the corpora to 3 and 9 o'clock, and then from superiorly another approximately 4 mm off the corpora as described in the earlier section on [Distal Hypospadias Repair](#) (see Fig. 147-11B).

Dissection along the ventral penile shaft is done immediately under the skin to preserve ventral dartos for a barrier flap. Degloving is not necessary unless there is excessive dorsal shaft skin or VC to revise.

If Mathieu or onlay flaps were previously done, this skin is now removed. Then the urethral plate is incised in the dorsal midline as with primary TIP repair and tubularized over a 6-Fr stent passed into the bladder. For distal reoperations, continuous subepithelial 7-0 polyglactin is used in two layers. More proximal reoperations have two-layer subepithelial urethroplasty using interrupted polyglactin followed by continuous polydioxanone. The neourethra is

next covered with either a ventral dartos flap or, if dartos is insufficient, a tunica vaginalis flap.

Glansplasty is done using subepithelial interrupted 6-0 polyglactin as described earlier for primary distal TIP urethroplasty. Excess ventral shaft skin is excised as needed and the skin edges are closed using subepithelial 7-0 polyglactin. The stent is maintained for 7 to 10 days.

Results

Urethroplasty complications were reported in 12% to 30% of patients after reoperative TIP repair. Prior urethral plate incision from either MAGPI or TIP repair does not impact outcomes. A dartos flap over the neourethra significantly reduced fistulas in one report.

Ninety percent of the patients in our series had distal hypospadias and failed an average of one prior repair (maximum of three) (Snodgrass et al, 2009). The indication for reoperation was glans dehiscence in 91%, with coronal fistulas, meatal stenoses, and diverticulum in the others. Initially I (W.S.) used a smaller incision and did not routinely cover the neourethra with a dartos flap, but after 5 of the first 10 cases developed fistulas a barrier layer was used systematically in all others, resulting in a significant reduction in fistulas (2 of 53 cases). Urethroplasty complications occurred in 12 of 63 patients (19%) with follow-up to a mean of 6 months (range 1 to 53), including seven fistulas and six recurrent glans dehiscences, before we implemented the extended glans wings dissection. Prior urethral plate incision from TIP urethroplasty or MAGPI (appendix) did not impact outcomes (Snodgrass et al, 2009).

A retrospective review by Ziada and colleagues (2006) had 30 TIP reoperations after a mean of 1.6 prior repairs (range 1 to 3) in which 63% were distal. Urethroplasty used subepithelial polyglactin covered by a dartos flap. During follow-up of more than 4 years there were nine complications (30%): eight meatal stenoses (five with fistulas) and one isolated fistula.

Another review included 40 patients for whom the meatal location and number of prior operations were not stated. During follow-up to a mean of 42 months, urethroplasty complications were diagnosed in 5 patients (12.5%) (Riccabona et al, 2003).

Dorsal Inlay Graft

Indications

This technique is used when the urethral plate has been removed but a strip of grossly healthy skin remains in its place. It is also used for neourethral strictures unless the lumen is nearly obliterated such that a dorsal incision and grafting are not practical.

Surgical Technique

The operation is done as described for TIP reoperations. The skin strip substituting for the urethral plate is incised dorsally as for TIP urethroplasty, but then the defect created is grafted using oral mucosa harvested from the upper lip for small grafts or the lower lip for longer grafts (Fig. 147-30). The visible margin of the lip is marked and two 5-0 polypropylene stays are placed to retract it open. The desired graft is outlined, injected with 1:100,000 epinephrine, and harvested. The graft is defatted. A small graft is easiest to handle by wetting a small area on the paper drapes, which holds it still. Then it is sewn to the perimeter of the incision using 7-0 polyglactin and quilted in the midline with 6-0 polyglactin on an RB-1 needle, which readily punctures the graft and secures it to the underlying tunica albuginea of the corpora. Urethroplasty, glansplasty, and skin closure then proceed as in TIP reoperations.

Results

Three reports all found urethroplasty complications in 15% of patients after inlay graft reoperation.

Figure 147-29. Ventral incision for hypospadias reoperations. Ventral incision for reoperative urethroplasty and glansplasty provides exposure to ventral dartos for barrier flap and facilitates cosmetic skin revision without need to deglove the penis.

Figure 147-30. Inlay graft. A, Skin strip has been incised dorsally as for tubularized incised plate repair. B, Oral mucosa graft is sewn into the defect. Tubularization for single-stage repair is done next.

Our report with 133 reoperations included only 16 patients (12%) meeting criteria for inlay grafts (Snodgrass et al, 2009). The meatus was distal in 62% and the mean number of failed repairs was 1.9 (range 1 to 9). Indications were glans dehiscence in 15 patients and meatal stenosis with a diverticulum in 1 patient. Urethroplasty complications developed in 2 of 13 patients (15%) with follow-up: one recurrent glans dehiscence and one fistula (Snodgrass et al, 2009).

A retrospective report by Ye and colleagues (2008) included 53 patients with an average of 2 failed repairs (range 1 to 6). Seventy percent had strictures; the remainder had glans dehiscence. Mean graft length was 5 cm taken from the lower lip. Urethroplasty complications occurred in 8 patients (15%) during follow-up for a mean of 23 months: five fistulas and three recurrent strictures all at the proximal junction to the urethra.

Another review had 32 patients with an average of 4 failed repairs (range 1 to 18). Skin grafts harvested from prepuce, penile shaft, or groin were used with a mean length of 4 cm (range 1 to 15). Complications developed in 16% during follow-up to a mean of 30 months: one fistula and four strictures at the proximal urethral junction (Schwentner et al, 2006).

It is not clear from the reports by Ye and colleagues and Schwentner and coworkers why strictures occurred at the proximal junction to the urethra. We reduce likelihood for this complication by extending the midline dorsal incision approximately 5 mm into the normal urethra.

Two-Stage Oral Mucosa Graft

Indications

This reoperation is used when the urethral plate or skin substitute is grossly scarred, or there is VC greater than 30 degrees, BXO, strictures that nearly obliterate the lumen, or hair in the neourethra.

Surgical Technique (Fig. 147-31)

The same initial ventral Y incision is made as described earlier for other reoperations, re-creating glans wings and opening the median raphe. Then the entire neourethra is excised until normal urethra is

encountered. All scarred ventral tissues are excised from the corporal surface, which also reestablishes a groove between the glans wings. Polypropylene stays are placed into the glans wings at the corona on either side.

Most often VC is corrected by removal of the neourethra and scarred tissues, but when it persists ventral transverse corporotomies and/or dorsal plication are used for straightening as described in the section on [Ventral Curvature](#) earlier in this chapter. The native urethra is spatulated ventrally and proximal urethrostomy is done, suturing penile shaft skin or scrotum to the urethra at 4, 6, and 8 o'clock. Intravenous cefazolin is given before graft harvest. We do not prep the mouth or change gloves after harvest. The visible margin of the lower lip is marked and two 5-0 polypropylene stay stitches are placed to pull the lip down. A damp gauze is packed over the tongue to prevent blood from entering the throat. All available tissue should be harvested from near the gum line to near the vermilion border and laterally on either side where the lip joins the cheek (Fig. 147-32). This extent of graft will cover from the tip of the glans to deep within the scrotum. The graft is injected with 1:100,000 epinephrine and harvested. A gauze soaked in 1:1000 epinephrine is laid onto the harvest site to aid in hemostasis.

The graft is defatted and then laid into the defect. The distal end is secured first, suturing the graft to the glans near the stays using interrupted, epithelial 7-0 polyglactin. Then the graft is stitched along the distal edge of the glans with subepithelial sutures to prevent marks at the site of the future meatus. The graft is gently stretched proximally and secured to the shaft skin along its perimeter with 7-0 polyglactin. The proximal end is incised in the midline and each arm is extended to either side of the urethrostomy (Fig. 147-33). The graft is then quilted to the underlying tunica albuginea of the corpora using 6-0 polyglactin on an RB-1 needle. Sutures are placed at 1-cm intervals beginning in the midline and then on either side (see Fig. 147-33C).

Next, 5-0 polypropylene stitches are placed on either side near the urethrostomy and at intervals distally. A rolled Vaseline gauze gently compresses the graft, held into place by these stays tied over it. The tie-over bandage and a catheter in the urethrostomy are maintained for 1 week. The donor site is left untreated to re-epithelialize spontaneously.

1st stage

2nd stage

Figure 147-31. Two-stage buccal graft reoperation. A, Neourethra opened with ventral incision. B, All unhealthy tissues, usually entire neourethra, are excised. C, Deep glans groove reestablished and proximal urethrostomy completed. D, Buccal graft quilted into place from meatus to glans tip. Lip is used within the glans and subcoronal region, and cheek along the penile shaft. The junction of lip to cheek is made diagonally to minimize contraction. E, U-shaped incision along perimeter of neourethra 6 months later. F, Two-layer tubularization of the neourethra using interrupted subepithelial polyglactin followed by continuous polydioxanone. G, Barrier flap, usually tunica vaginalis, covers the entire neourethra. H, Glansplasty and skin closures completed with subepithelial sutures. (From Snodgrass W, Elmore J. Initial experience with staged buccal graft [Bracka] hypospadias reoperations. *J Urol* 2004;172(4 Pt. 2):1720-4.)

There is no need for any care of the revascularizing graft between stages. We always wait for 6 months before performing the second stage of the urethroplasty. In less than 10% of cases the graft will scar or contract such that partial or complete regrafting is required (Fig. 147-34). Focal narrowing can be corrected during the second stage either by inlay grafting or by incorporating shaft skin into the neourethra. At the second stage the oral mucosa is outlined with a marker and the glans wings are injected with 1:100,000 epinephrine. The wings and shaft skin are dissected from the neo-urethral plate. There is little need to dissect under the neoplate because usually its edges are sufficiently mobile for approximation. It is then tubularized using 6-0 polyglactin interrupted subepithelial stitches followed by continuous 6-0 polydioxanone for two-layer closure.

A testicle is exposed and tunica vaginalis harvested for a barrier flap as described earlier in the chapter. Then glansplasty is done with 6-0 polyglactin, and skin edges are closed with subepithelial stitches. The catheter remains for 2 weeks. Typical cosmetic results are shown in Figure 147-35.

Results

Graft Take. Graft contractures requiring regrafting occur in less than 10% of two-stage oral mucosa graft reoperations.

Snodgrass and colleagues (2009) reported the need for additional grafting in 5 of 48 cases (10%), requiring a patch in 4 and complete replacement in 1. Since that report we changed to the

lower lip as the donor site and harvested larger grafts. In the next 63 patients, 2 (3%) had regrafting for contractures. Because some extent of contracture can occur with grafts, we now harvest the largest piece available within the donor site, and then excise any excess during the second stage.

Two retrospective series also reported regrafting before tubularization. One noted partial graft loss needing regrafting in 2 of 34 (6%) buccal mucosa grafts (Gill and Hameed, 2011) and the other found 4 of 30 (13%) cheek and/or lip grafts requiring regrafting (Leslie et al, 2011).

Urethroplasty Complications. Urethroplasty complications were reported in up to 38% of patients after the second stage.

Snodgrass and colleagues (2009) reported urethroplasty complications after the second stage in 17 of 45 (38%) patients with follow-up. These included glans dehiscence ($n = 8$), fistulas ($n = 7$), and meatal stenosis ($n = 2$). All glans dehiscences in this series occurred when cheek, rather than lip, was used, possibly because

grafts from the cheek are visibly thicker, making glans closure more difficult and tenuous (Fig. 147-36). Dehiscence likely also related to glans width, because most of these reoperations were in patients born with proximal hypospadias, but we did not measure the glans at that time. We have subsequently observed glans dehiscence following two-stage graft repairs despite using lip mucosa. Therefore we continue to harvest lip but routinely additionally perform the more extended glansplasty we have described throughout this chapter at the second stage to reduce risk for this complication.

The series published by Gill and Hameed (2011) included a total of 100 patients, with most having two-stage grafting using other graft sources such as prepuce, postauricular skin, and medial upper arm skin. They did not report the total number of patients with complications but stated there were nine fistulas, six strictures, six patients with persistent hypospadias (most likely dehiscence), and four patients with persistent VC. Leslie and colleagues (2011) found complications in 11 of 30 (37%) cases: meatal stenosis in 5, fistulas in 3, and glans dehiscences in 3.

Figure 147-32. Labial graft harvest. Outline for graft harvest from lower lip, extending from the gum to within approximately 3 mm of the visible border of the lip. This graft will surface from the glans to the penoscrotal junction, or more proximally, in boys. The donor site is not sutured.

ADULT OUTCOMES AFTER PREPUBERTAL REPAIR

Despite the obvious need for information regarding urinary and sexual function in adults following hypospadias repair in childhood, few data are available. Rynja and colleagues (2011) conducted a systematic literature review through 2010 to determine outcomes in men of mean age 27 years operated for hypospadias at less than 6 years of age. Twenty studies with 1069 patients were included. The mean number of surgeries was 2.7, and proximal repair outcomes were available from 180 men. Procedures used included Ombredanne, Denis Browne, van der Meulen, and Cecil-Culp (no longer widely used), as well as MAGPI and Mathieu procedures, onlay and tubularized preputial flaps, and Byars flaps. There were 742 controls with mean age of 20 years. At this time there are no similar data for TIP outcomes in adults operated as children.

Urinary Function

Symptoms

Patients reported significantly more obstructive symptoms (77 of 217 [35.5%] vs. 30 of 196 [15%]), spraying (245 of 818 [30%] vs.

Figure 147-33. Oral mucosa graft. A, A single piece of lower lip graft has been used to fill the defect from the glans to within the scrotum. B, Note the extensions of graft to either side of the proximal urethrostomy. C, The graft is quilted and next a tie-over bandage will be placed.

Figure 147-34. Graft scar and contracture. A, Stellate scar in midportion of graft. B, Distal graft contracture. C, Desired healthy appearance of well-vascularized graft. (From Snodgrass W, Elmore J. Initial experience with staged buccal graft [Bracka] hypospadias reoperations. *J Urol* 2004;172(4 Pt. 2):1720–4.)

Figure 147-35. Cosmetic outcomes after two-stage buccal graft reoperation. (From Snodgrass W, Elmore J. Initial experience with staged buccal graft [Bracka] hypospadias reoperations. *J Urol* 2004;172(4 Pt. 2):1720–4.)

17 of 231 [7%]), and deviated stream (69 of 267 [26%] vs. 9 of 81 [11%]) than did controls. Those with proximal hypospadias had more spraying (46 of 106 [43%]) than did patients with distal repairs (245 of 818 [30%]).

Uroflowmetry

Qmax was significantly less in patients than controls (mean 24 mL/sec vs. 30 mL/sec), as was Qmax less than two standard deviations (36 of 265 [13.5%] vs. 4 of 138 [3%]). Patients with proximal

hypospadias had significantly lower Qmax (mean 21 mL/sec) than did those with distal hypospadias.

Sexual Function

Ejaculation

Ejaculation problems, including milking semen and poor force, were significantly more common in patients than controls (99 of 385 [26%] vs. 0 of 48, $P < .01$).

Figure 147-36. Cheek versus lip grafts. A, Cheek mucosa grafts are thicker and may complicate glansplasty. B, Labial grafts are thinner with significantly less likelihood for glans dehiscence.

Sexual Satisfaction

Patients were less satisfied with sexual function than controls (153 of 188 [81%] vs. 235 of 252 [93%], $P < .01$). Mean frequency of intercourse per month did not vary (5.8 vs. 6.4).

Cosmesis

Patients were more likely to be dissatisfied with penile appearance (143 of 493 [29%]) than were controls (24 of 581 [4%]). Those with proximal hypospadias were more dissatisfied with penile appearance than those with distal hypospadias (25 of 46 [54%] vs. 143 of 493 [29%]).

IMPROVING OUTCOMES

Upon relocating to Dallas in 1999, I (W.S.) began recording data prospectively into Excel spreadsheets. The articles referenced in this chapter since that date are all based on analysis of these databases, which today contain information on more than 1600 consecutive patients. Reviews of these data have improved our surgical techniques, outcomes, and understanding of the underlying factors that impact results in hypospadias repair.

Determining Results

At this time there is no computer software that connects preoperative, intraoperative, and postoperative data to create a surgeon scorecard, but with the growing reliance on electronic medical records it is only a matter of time before this occurs. Meanwhile, surgeons can enter pertinent data into an Excel spreadsheet to rapidly determine their personal outcomes. Recognizing the factors that best predict urethroplasty complications, a surgeon need only enter the patient name, date of operation, meatal location, glans width, primary versus reoperation, operative procedure, date of follow-up, and any complication noted. Depending on individual volume of repairs, that surgeon will learn his or her complication rate using reliable data within as little as 1 year at a cost of only a few minutes a week to enter the information after surgery or clinic.

Technical Changes

When surgeons decide to perform a quality assessment of their surgical outcomes, whether of hypospadias or other conditions, they most often learn there are opportunities for improvement. For example, I (W.S.) was surprised that my fistula rate after proximal

TIP urethroplasty was 25% despite using a dartos flap over the neourethra. However, these cases are relatively infrequent for most pediatric urologists, who according to the American Board of Urology perform an average of two per year, and so even this high a complication rate may go undetected because patients with complications present sporadically and recall bias limits our ability to tabulate them without spreadsheets or chart review. Having recognized this, I (W.S.) made a series of technical modifications described in this chapter that significantly reduced my fistula rate.

We similarly noted glans dehiscence at rates higher than reported, and initially thought it might be due to glans wings approximation using chromic catgut. I (W.S.) therefore changed to polyglactin, but subsequent multivariable analysis, made possible by ongoing data collection, showed that suture type did not impact this complication, which was seen to be more common in proximal than distal repairs despite the same surgeon using the same technique for glansplasty. That led to measurements of glans size, which confirmed suspicions that dehiscence and other urethroplasty complications were more prevalent when glans width was less than 14 mm. Knowing androgens will increase glans circumference, we embarked on a program of preoperative testosterone injections for the small glans. We learned that this objective patient selection resulted in double the number of boys receiving stimulation compared to our previous subjective use for a “small-appearing” glans. We also encountered unexpected androgen resistance in two thirds of those treated, requiring injections greater than 2 mg/kg to achieve targeted growth to 15 mm or greater. Most importantly, further outcomes review ultimately found that despite growing the glans to a size previously determined to have low complication rates, those patients who needed stimulation continued to have significantly more dehiscence than other boys whose glans was the desired size without stimulation. Because reduction in complications, not growth of the glans, was the aim of therapy, we then stopped androgen treatment.

This focus on glans size and dehiscence made me (W.S.) more aware of variations in glans wings dissection, and more receptive to change in my technique. When I observed two senior Japanese surgeons perform a more extended glans wings mobilization, I recognized its potential and incorporated it into our practice.

Improving Results

Prospective data collection, periodic outcomes review, and practice changes such as these make us better hypospadiologists and improve results for the young patients entrusted to our hands.

Of these, data collection is most important, because once a surgeon learns his or her actual results from data he or she knows

are reliable, changes in technique and improved outcomes inevitably follow. Conversely, if low complication rates are found, a surgeon benefits from knowing there is no need to change current practice, which is especially useful should a cluster of complications occur that otherwise might raise doubts. This is the core of evidence-based surgical practice.

Embryology of Testicular Development and Descent

Etiology

Diagnosis

Management

Prognosis

Cryptorchidism, or undescended testis, is a common genital anomaly that is extensively studied yet incompletely understood. Testicular descent is a complex and prolonged gestational event that is completed in the third trimester, or soon after birth. The fetal structure that orchestrates descent of the testis, the gubernaculum, is anatomically but not functionally well characterized. The genetic and/or environmental factors that contribute to failure of testicular descent remain largely unknown. Cryptorchidism was traditionally considered a congenital anomaly identifiable at birth, but more recent evidence confirms that an initial diagnosis well beyond the neonatal period is not uncommon. Clinically significant differences, if any, between the acquired and congenital presentations of cryptorchidism remain obscure. Present evidence supports surgery as the preferred treatment approach and provides improved understanding of the long-term risks, including impairment of fertility potential and testicular cancer.

DEFINITIONS

Because differing terminology is used to describe conditions related to normal and abnormal testicular descent and absence of a testis in the scrotum, we provide definitions for the following terms that are used throughout the chapter:

- **Normal scrotal position** has been defined as positioning of the midpoint of the testis at or below the midscrotum (Wohlfahrt-Weje et al, 2009). Although “high scrotal testes” are not routinely considered undescended by most clinicians, they have been included in the definition of undescended testis in some epidemiologic studies (Sijstermans et al, 2008). This is likely a heterogeneous group that includes stable descended testes that reside above the scrotal midpoint and retractile and undescended “gliding” testes (Hack et al, 2007), which are not stable.
- **Undescended testis** or **cryptorchidism** is the absence of one or both testes in normal scrotal position and during initial clinical evaluation may refer to palpable or nonpalpable testes, which are either cryptorchid or absent. Most absent testes are *vanishing* or *vanished*, being present initially in development but becoming lost as a result of vascular accident or torsion unilaterally (*monorchia*) or, very rarely, bilaterally (*anorchia*) (Abeyaratne et al, 1969).
- **Agenesis** refers to a testis that was never present and therefore is associated with ipsilateral müllerian duct persistence.
- **Congenital cryptorchidism** refers to testes that are extrascrotal at birth.

- **Acquired cryptorchidism** is defined as cryptorchid testes that were documented as scrotal at a previous examination without intervening inguinal surgery.
- **Recurrent cryptorchidism** is defined as cryptorchid testes that were undescended at birth, descended spontaneously, and are subsequently defined as extrascrotal.
- **Secondary cryptorchidism** and **testicular retraction** have been used to describe testes that are suprascrotal after inguinal hernia repair and as a complication of orchidopexy, respectively. Testicular malposition after hernia repair could be caused by either post-operative scarring or primary maldescent.
- **Retractile testes** are scrotal testes that retract easily out of the scrotum but can be manually replaced in a stable scrotal position and remain there at least temporarily until there is recurrent stimulation. Testes that are significantly retractile—that is, those that rarely remain in a stable scrotal position (spontaneously or with manipulation) and/or are located at rest in the high scrotum—may or may not be diagnosed as cases of acquired cryptorchidism on longitudinal examination.

EMBRYOLOGY OF TESTICULAR DEVELOPMENT AND DESCENT

Cryptorchidism represents a failure of testicular descent, which is in turn dependent on growth and hormonal function of the developing testis. Testicular descent is regulated by two Leydig cell hormones—insulin-like 3 (INSL3) via its receptor relaxin/insulin-like family peptide receptor 2 (RXFP2), and androgens via the androgen receptor (AR)—but downstream pathways are poorly defined. Altered expression or function of key molecules that participate in testicular and/or gubernacular development, as a result of genetic or environmental effects, could potentially contribute to an increased risk of cryptorchidism.

Differentiation of the Testis

Gonadal differentiation is more complicated than the original concept of ovarian development as the default pathway. Activation of specific genetic programs is required for both male and female sex determination in mice (Sekido and Lovell-Badge, 2013; Ungewitter and Yao, 2013). Although basic work has moved the field substantially forward in recent years, the mechanisms of cell-specific development in the testis remain incompletely understood (Svingen and Koopman, 2013). In the fetal mouse,

Figure 148-1. Circulating male hypothalamic-pituitary-gonadal axis hormones from conception to puberty. Schematic view shows the rise in testosterone (T), insulin-like 3 (INSL3), luteinizing hormone (LH), follicle-stimulating hormone (FSH), and antimüllerian hormone (AMH) during early fetal life; secondary elevation of these hormones and of inhibin B soon after birth; and suppression of AMH at puberty. (Modified from Grinspon RP, Ropelato MG, Bedecarras P, et al. Gonadotrophin secretion pattern in anorchid boys from birth to pubertal age: pathophysiological aspects and diagnostic usefulness. *Clin Endocrinol [Oxf]* 2012;76:698–705.)

Sry (sex-determining region on the Y chromosome) expression in the indifferent gonad triggers testicular development and is activated in part by steroidogenic factor 1 (*Nr5a1/SF1*). In turn, SRY and SF1 proteins cooperate to promote prolonged expression of another transcription factor, SOX9 (SRY-box containing 9), in pre-Sertoli supporting cells. SRY is important for Sertoli cell specification, but downstream testis-determining genes including *Sox9*, *Fgf9* (fibroblast growth factor 9), *Amh* (antimüllerian hormone) and *Ptgds* (prostaglandin synthase) are required for Sertoli cell differentiation and proliferation (Kashimada and Koopman, 2010). Establishment of the Sertoli cell lineage is required for subsequent testicular cord formation. Studies in the fetal mouse indicate that patterning of the testis requires a temporal series of events that includes germ cell migration into the undifferentiated gonad and migration of interstitial cell precursors from the coelomic epithelium and the mesonephros (Combes et al, 2009; Cool and Capel, 2009; Wainwright and Wilhelm, 2010; McClelland et al, 2012).

In humans, gonads containing somatic and germ cells are first identified on the medial aspect of the urogenital ridge at 32 days postovulation (Hanley et al, 1999). At this sexually indifferent stage, the gonads and the internal and external genitalia are identical in males and females. Expression of SRY and SOX9 transcripts begins at 41 to 44 days (Hanley et al, 2000), followed by the histologic appearance of Sertoli cells (Ostrer et al, 2007). By 6 weeks' gestation, primordial germ cells migrate from the yolk sac and differentiate into gonocytes and by 8 weeks' gestation are localized within the testicular cords (Culty, 2009). Gonocytes become c-KIT+ at 7 weeks, and their numbers increase further during the remainder of the first trimester (Ostrer et al, 2007). During the second trimester, three subpopulations of germ cells, including gonocytes, intermediate spermatogonia, and prespermatogonia, can be distinguished by immunostaining for specific markers (Gaskell et al, 2004). POU5F1 (POU domain class 5 homeobox 1, also known as OCT4) and c-KIT are expressed in the earlier lineages and disappear with loss of gonocytes by 20 weeks, whereas gain of MAGE-A4 (melanoma antigen, family A, 4) immunopositivity occurs with emergence of prespermatogonia (Gaskell et al, 2004; Culty, 2009). Leydig cells become active at 6 to 7 weeks' gestation, proliferate until about 15 weeks, and involute after 24 weeks (Codesal et al, 1990; Habert et al, 2001; O'Shaughnessy et al, 2007). Before the end of the first trimester of gestation, the external genitalia are completely masculinized, the testis cords are established, and subpopulations of both proliferating and degenerating germ cells exist.

Sertoli and germ cell proliferation continues well into the second trimester (O'Shaughnessy et al, 2007).

Testicular Hormone Production

Hormonal function of the human fetal testis is critical for masculinization of the reproductive tract and testicular descent. Activation of testicular hormone production occurs at discrete intervals during fetal, postnatal, and pubertal life (Fig. 148-1). In the fetus, Leydig cell development is divided into three phases: a proliferation and differentiation phase at 7 to 14 weeks' gestation, a maturation phase until 18 weeks' gestation, and an involution phase that continues until term (Svechnikov and Soder, 2008). Synthesis of testosterone by fetal Leydig cells starts as early as 6 to 7 weeks' gestation and appears to be initially independent of gonadotropin stimulation. However, placental human chorionic gonadotropin (hCG) stimulates a peak in androgen production at 14 to 16 weeks, and the testis then becomes responsive to fetal luteinizing hormone (LH). INSL3 of Leydig cell origin is measurable in human amniotic fluid as early as 13 weeks' gestation (the earliest time point studied) and peaks at 15 to 17 weeks (Anand-Ivell et al, 2008; Bay et al, 2008). Fetal Sertoli cells produce AMH (also called müllerian inhibiting substance [MIS]) soon after they differentiate; the human fetal müllerian duct is responsive to AMH before week 8 of gestation, and the process of regression occurs at 9 to 10 weeks (Josso et al, 2006). Steroid hormones exert their effects via sex steroid receptors in the reproductive tract and testis. Androgen receptor (AR) and estrogen receptor β (ER- β) are expressed in the undifferentiated gonad at 7 weeks of age, although their role in testis development is unclear (Shapiro et al, 2005; Boukari et al, 2007). AR is present primarily in peritubular myoid cells and in some Leydig and interstitial cells, but absent in Sertoli cells during early development. Lack of AR expression in fetal and early postnatal Sertoli cells is physiologically important, because its presence would allow inappropriate androgen-induced inhibition of AMH production and precocious stimulation of spermatogenesis (Boukari et al, 2009; Rey et al, 2009). ER- β expression in fetal testis is observed in germ, peritubular myoid, Sertoli, and some Leydig cells, whereas expression of estrogen receptor α (ER- α) is limited (Shapiro et al, 2005) or absent (Boukari et al, 2007) in human fetal testis. Concomitant expression of aromatase during the same time frame suggests that locally produced estrogen may play a role in testis development.

Reactivation of the hypothalamic-pituitary-gonadal (HPG) axis occurs during the neonatal period, a phenomenon known as “mini-puberty” (see Fig. 148-1) with cross-sectional data suggesting that peak hormone levels occur at 1 to 3 months of age. Serum LH and FSH levels rise postnatally, followed by increases in testosterone, AMH, and inhibin B; INSL3 levels are high in both cord blood and at 3 months of age (Andersson et al, 1998; Bergada et al, 2006; Bay et al, 2007; Aksglaede et al, 2010). However, individual longitudinal data indicate that postnatal urinary LH, FSH, and testosterone levels peak earlier, at or before 1 month of age, and are more pronounced in preterm boys (Kuiiri-Hanninen et al, 2011). Studies of the androgen insensitivity syndrome provide evidence that the postnatal hormone surge is a response to maternal androgen withdrawal with secondary activation of hypothalamic and pituitary hormones (Quigley, 2002). Fetal Leydig cells regress after birth, followed by emergence of a neonatal Leydig cell population at 2 to 3 months of age (Prince, 2001). As postnatal hormonal levels wane, the fetal Leydig cells either degenerate or regress to immature, partially differentiated Leydig or interstitial cells that are less responsive to LH.

The postnatal hormone surge is accompanied by increased testicular volume, primarily as a result of Sertoli and germ cell proliferation (Grumbach, 2005). Several studies show significant growth of testes during the neonatal period (Berensztein et al, 2002; Main et al, 2006b; Kuijper et al, 2008), and increased testicular growth rate and HPG axis activation are correlated in preterm boys (Kuiiri-Hanninen et al, 2011), suggesting that growth is a direct response to hormonal stimulation. Sertoli cell proliferation continues in the first year of life and is a major determinant of ultimate testicular size (Sharpe et al, 2003). Undifferentiated germ cells, called *prespermatogonia*, *prospertmatogonia*, or *gonocytes* (Culty, 2013; McCarrey, 2013), migrate to the basement membrane after birth and become established as undifferentiated type A spermatogonia. In humans and primates, type Ad and Ap spermatogonia include a subpopulation of spermatogonial stem cells (Hermann et al, 2010; Griswold and Oatley, 2013). Because migration occurs in a similar time frame to HPG axis activation, a relationship is presumed (Hadziseimovic et al, 1986; Hutson et al, 2012), but regulation of this important event remains poorly understood. Some factors shown to regulate migration of *prespermatogonia* or *gonocytes* include platelet-derived growth factor, thyroid hormone, and cell adhesion molecules (Orth et al, 2000; Tres and Kierszenbaum, 2005; Basciani et al, 2008; Oatley et al, 2011). If migration fails to occur, *prespermatogonia* or *gonocytes* are at increased risk for apoptosis or future malignant transformation (Rajpert-de Meyts and Hoei-Hansen, 2007).

Gubernacular Development and Testicular Descent

The physiology of normal testicular descent and the cause of abnormal descent in humans remain poorly understood, although the morphologic events have been well studied in mammals. Knowledge of the regulation of testicular descent is inferred from studies of human diseases that include cryptorchidism and/or from animal models of the disease.

The human indifferent gonad develops adjacent to and becomes suspended from the mesonephros, which has replaced the pronephros by 5 weeks' gestational age (Lemeh, 1960). A rudimentary cranial mesonephric ligament connects to the diaphragm, disappearing by 13 weeks as the mesonephros regresses (Barteczko and Jacob, 2000) (Fig. 148-2). There is no direct connection between the gonad and this ligament; therefore no cranial gonadal ligament exists in humans as noted in other species. Using fixed sections, Barteczko and Jacob observed an “inner” or transabdominal descent of the human testis from a position at vertebral levels C7-T8 to T9-L3 at 5 to 7 weeks' gestation and to sacral level by 10 weeks; using dissections, others described the testis at the level of L4 by the 7th week (Lemeh, 1960) or always “close to the groin” (Wyndham, 1943). Caudal movement of the ovary is prevented by the ovarian ligament and development of the müllerian ducts.

Barteczko and Jacob (2000) described five major phases of testicular descent in the human fetus (Fig. 148-3). In **phase I** (5 weeks

Figure 148-2. Development of the cranial mesonephric ligament (CML) and gonad (G) during embryonic regression of the mesonephros (M). Asterisks denote the anlage of the diaphragm. (From Barteczko KJ, Jacob MI. The testicular descent in human. Origin, development and fate of the gubernaculum Hunteri, processus vaginalis peritonei, and gonadal ligaments. *Adv Anat Embryol Cell Biol* 2000;156:iii-x, 1–98.)

of gestation), the caudal mesonephros contacts the future gubernaculum at the internal inguinal ring. In **phase II**, the genitofemoral nerve (GFN) is seen to accompany the newly formed gubernaculum (abdominal, interstitial, and subcutaneous portions) and processus vaginalis (7 weeks); subsequently, growth of the gubernaculum, deepening of the processus vaginalis, and extension of cremaster muscle fibers into the interstitial gubernaculum occur (8 to 10 weeks). In **phase III** (10 to 14 weeks), growth of the testis and regression of the müllerian ducts and mesonephros occur; the gubernaculum is visible as a thin cord in both sexes and begins its swelling phase in males after 12 weeks. In **phase IV** (14 to 20 weeks), swelling of the gubernaculum, further development of the cremaster muscle, and migration of the processus vaginalis produce widening of the inguinal canal. In **phase IV** (20 to 28 weeks), release of the distal subcutaneous attachment of the gubernaculum and transinguinal passage of the testis occur. Further caudal movement of the testis into the scrotum up until the time of birth is accompanied by regression of the gubernaculum.

The careful in situ anatomic observations by Barteczko and Jacob (2000) throughout gestation help clarify some aspects of human testicular descent. For example, transabdominal movement of the testis occurs before sexually dimorphic changes in the gubernaculum and thus is presumably not a male hormone-specific event. The subsequent male-specific swelling of the gubernaculum parallels the peak in Leydig cell secretion of testosterone (14 to 16 weeks) and INSL3 (15 to 17 weeks). The GFN precedes and accompanies the gubernaculum and developing processus vaginalis in both sexes beginning at an early stage (7 weeks), and both smooth muscle (in the abdominal portion) and skeletal muscle (in the interstitial and subcutaneous portion) fibers are present within these three segments of the gubernaculum. Both muscle types were also observed by other (Wyndham, 1943; Lemeh, 1960) but not all (Heyns, 1987; Costa et al, 2002; Niikura et al, 2008) researchers. However, studies of the in situ gubernaculum beginning at 20 weeks clearly show the presence of peripheral and centrally located striated muscle bundles (Barteczko and Jacob, 2000; Niikura et al, 2008) and infiltration of the gubernaculum by the GFN (Tayakkanonta, 1963). Controversy exists as to whether skeletal cremaster muscle fibers originate from abdominal wall musculature or from within the gubernaculum itself (van der Schoot, 1996; Barteczko and Jacob, 2000; Niikura et al, 2008), but their unique innervation and recent studies of transgenic mice (see later) suggest the latter.

Swelling of the gubernaculum is critically important to allow enlargement of the inguinal canal and testicular passage and is the result of both cellular proliferation and production of extracellular matrix (Heyns, 1987). Once the canal is created, unknown mechanical factors trigger a typically rapid transinguinal passage of

Figure 148-3. Overview of human testicular descent. Sagittal view (*top*) and transverse sections (*bottom*) at level of double line; 1, gonad; 2, mesonephros; 3, wolffian and müllerian duct; 4, vas deferens and epididymis; 5, gubernaculum—a, abdominal; i, interstitial; s, subcutaneous part; 6, processus vaginalis; 7, internal inguinal ring; 8, external inguinal ring. *Straight arrows* (phase I) show ventral side; *asterisks* (I to IIIa) show the link between the caudal pole of the testis and dorsal mesenchyme of genital ducts; *curved arrow* (III) shows direction of testicular migration; *short arrows* (IIIa to IV) indicate attachment between the testis or epididymis and gubernaculum; *oval arrowline* (V) indicates no connection between the boltlike gubernaculum and neighboring structures. (From Barteczko KJ, Jacob MI. The testicular descent in human. Origin, development and fate of the gubernaculum Hunteri, processus vaginalis peritonei, and gonadal ligaments. *Adv Anat Embryol Cell Biol* 2000;156:iii–x, 1–98.)

the testis. The gubernaculum is unattached distally during and after transinguinal passage (Fig. 148-4), and settling of the gubernaculum and testis into the preformed scrotum is gradual. The scrotum itself develops from genital swellings that are first visible at 7 weeks and fuse by 10 to 12 weeks in response to circulating dihydrotestosterone. Passage of the testis into the inguinal canal rarely occurs before 22 weeks in the human fetus, and the majority of testes are scrotal after 27 weeks; time spent in the inguinal canal seems to be limited for the majority of human fetal testes (Heyns, 1987; Sampaio and Favorito, 1998). The rapidity of transinguinal testicular transit, early innervation of the gubernaculum in human fetuses (Barteczko and Jacob, 2000), significance of the GFN in rodents (Hutson and Hasthorpe, 2005), and the complex anatomic distribution of cremaster muscle in and around the gubernaculum (Harnaen et al, 2007; Niikura et al, 2008) suggest that neuromuscular forces are required for testicular descent.

Regulation of Testicular Descent

Direct evidence for hormonal control of testicular descent is based on studies in animal models, primarily rodents. The relevance of rodent data to humans has been questioned because of anatomic differences, which in mice and rats include a less prominent interstitial gubernaculum, a cranial gonadal ligament, an elongated cord connecting the gubernaculum to the epididymis, a well-developed intrinsic cremaster muscle located in the periphery of the gubernaculum, an absent inguinal canal, and failure of closure of the processus vaginalis (Wensing, 1988). However, the developing processus vaginalis and cremaster muscle are sufficiently anatomically similar among species to warrant translational studies using rodent models (van der Schoot, 1996; Harnaen et al, 2007), and their normal development is essential for testicular descent.

Evidence from animal models and indirect clinical evidence suggest that *INSL3* and testosterone are the key hormones required for testicular descent. Transgenic or spontaneous rodent strains with inactivation of *Insl3*, *Rxfp2*, or *Ar* are cryptorchid (Zimmermann et al, 1999; Adham et al, 2000; Overbeek et al, 2001), as are boys with abnormalities of androgen synthesis or action (Barthold et al, 2000; Foresta et al, 2008; Gaspari et al, 2011). According to a paradigm developed by Hutson and

Figure 148-4. The distally unattached human gubernaculum just before transinguinal passage. Human fetus at 25 weeks of gestation (215-mm crown-rump length) just before transinguinal testicular descent. G, gubernaculum; P, penis; S, scrotum; T, testis. (From Heyns CF. The gubernaculum during testicular descent in the human fetus. *J Anat* 1987;153:93–112.)

colleagues, testicular descent occurs in two phases, transabdominal and transinguinal, regulated by INSL3 and by androgens via the GFN, respectively (Hutson and Hasthorpe, 2005). However, animal models show that INSL3 and androgen synergistically stimulate cellular proliferation and growth of the gubernaculum (Adham et al, 2000; Emmen et al, 2000; Kubota et al, 2002) and that both INSL3 binding and AR expression are present before and during the swelling phase of the fetal rat gubernaculum (Staub et al, 2005). Moreover, INSL3 and testosterone levels peak after 12 weeks in the human fetus, concomitant with gubernacular swelling, whereas transabdominal testicular descent occurs earlier, before 10 weeks' gestation (Barteczko and Jacob, 2000; Koskimies et al, 2003; McKinnell et al, 2005). In mice, INSL3 signaling also promotes development of the processus vaginalis, and androgen signaling causes regression of the cranial gonadal ligament (Adham et al, 2002; Koskimies et al, 2003; Adham and Agoulunik, 2004), a structure that does not exist in the human fetus.

More recent data suggest that both INSL3/RXFP2 and AR signaling are directly involved in development of the gubernaculum, specifically in myogenic differentiation of the cremaster. In transgenic mice with conditional deletion of *Rxfp2* or *Ar* in the gubernacular mesenchyme (but not differentiated muscle), testicular descent is disrupted (Kaftanovskaya et al, 2011, 2012). In the gubernaculum-specific *Rxfp2*^{-/-} transgenic mice, aberrant muscle cells exist within the developing mesenchymal core of the gubernaculum, and the cremaster muscle fails to develop normally, suggesting that proliferation, migration, and patterning of muscle precursors depend on INSL3/RXFP2 signaling. Moreover, migration and proliferation of AR-positive cells into the gubernaculum fail to occur normally in conditional *Rxfp2*^{-/-} fetuses, suggesting interaction between the RXFP2 and AR pathways. The defect in cremaster development is less severe with conditional deletion of *Ar* in gubernacular mesenchyme; however, muscle organization and growth are impaired, expression of muscle-specific markers is altered, and testicular descent fails to occur (Kaftanovskaya et al, 2012).

The definition of pathways and mechanisms of gubernacular development and testicular descent downstream of hormone signaling are provided by transgenic mouse models and human syndromes with phenotypes that include cryptorchidism (Barthold, 2008; Foresta et al, 2008). A theme that again emerges from these studies is the importance of myogenesis in gubernacular development. In mice, transgenic inactivation of genes including *Notch1* and several involved in Wnt pathway signaling, including *Ctnnb1*, *Sfrp1*, *Sfrp2*, *Wnt5a*, and *Ror2*, results in marked disruption of fetal muscle patterning (Warr et al, 2009; Kaftanovskaya et al, 2011; Chawengsaksophak et al, 2012). Gene expression in fetal rat gubernaculum after stimulation by dihydrotestosterone (Barthold et al, 2013) or INSL3 (Johnson et al, 2010) also supports activation of Wnt pathways by both hormones and strong overlap in their transcriptional response. Transgenic deletion of either of two homeobox genes, *Hoxa10* and *Hoxa11*, is associated with isolated cryptorchidism in mice (Satokata et al, 1995; Potter and Brannford, 1998) with evidence for delayed muscle development in the *Hoxa11* gubernaculum (Harisis et al, 2013). Also, the cremaster muscle is overdeveloped and associated with retractile testes in *Esr1* knockout mice (Donaldson et al, 1996). Other transgenic mouse models that include the cryptorchid phenotype provide insight into pathways required for testicular descent. These include targeted deletions of *Tgfb2* (Sanford et al, 1997), *Arid5b* (Lahoud et al, 2001), *Wt1* (Kaftanovskaya et al, 2013), *Ptgs* (Philibert et al, 2013), and *Loxl1* (Wood et al, 2009) and spontaneous mutations of *Ptch1* (Sweet et al, 1996) and *Bmp5* (Green, 1968).

Studies of rats with inherited cryptorchidism also suggest that innervation and/or muscle development within the gubernaculum is disrupted (Hrabovszky et al, 2001; Barthold et al, 2008), and recent three-dimensional images of the cryptorchid rat gubernaculum show muscle patterning defects (Barthold et al, 2014). Based on extensive rodent studies, Hutson and colleagues have shown that gubernacular innervation by the GFN is essential for its function, and they propose that release of calcitonin gene-related peptide (CGRP) from the GFN stimulates development and func-

tion of the gubernaculum (Yamanaka et al, 1993; Chan et al, 2009). Although a role for CGRP release from the GFN in human fetuses remains undefined, it is clear that the human gubernaculum contains and is surrounded by muscle and is innervated by the GFN beginning as early as 7 weeks' gestation (Lemeh, 1960; Tayakanonta, 1963; Barteczko and Jacob, 2000; Niikura et al, 2008).

In summary, the gubernaculum develops in both sexes beginning early in the second month of gestation, and the testicular hormones INSL3 and androgen stimulate development of the gubernaculum and testicular descent in the second and third trimesters. Enlargement and migration of the gubernaculum are key events that facilitate and direct caudal movement of the testis. INSL3 and androgens appear to synergistically target cellular proliferation, migration, and muscle patterning within the gubernaculum, in part via Wnt signaling. A consistent theme in experimental models of cryptorchidism is altered myogenesis of the cremaster, suggesting an important role in the process of testicular descent.

ETIOLOGY

The specific cause of isolated cryptorchidism is unknown in most cases, but indirect evidence suggests that the disease is heterogeneous and most likely the result of multiple genetic and environmental risk factors. Human data do not suggest strong genetic risk at a dominant locus but rather a multilocus, complex pattern of genetic susceptibility. Also, available human data have not identified any clear and consistent exposures associated with the disease, although animal models suggest that certain environmental chemicals have the potential to contribute to cryptorchidism risk. The most consistent perinatal factors correlating with risk of cryptorchidism are prematurity and/or low birth weight for gestational age (Damgaard et al, 2008; Bay et al, 2011; Brouwers et al, 2012; Jensen et al, 2012).

Epidemiology

Cryptorchidism is one of the most common congenital anomalies, occurring in 1% to 4% of full-term and 1% to 45% of preterm newborn boys (Sijstermans et al, 2008). It is a component of almost 500 syndromes causally linked, based on current information, to almost 200 genes according to the Winter-Baraitser Dysmorphology Database (www.lmddatabases.com); the most common associated syndromes are reviewed elsewhere (Foresta et al, 2008; Virtanen and Toppaari, 2008). The majority of cases are isolated, with the ratio of nonsyndromic to syndromic cryptorchidism reported as greater than 6:1 in a large cohort (Boyd et al, 2006). A subset of syndromic cases is associated with deficiency or insensitivity of HPG axis hormones.

Congenital Cryptorchidism

Studies of the prevalence of isolated cryptorchidism at birth are complicated by confounding factors that include subjectivity of the examination and differences in the definition of undescended testis (inclusion or exclusion of high scrotal testes), study populations, and experimental design (Sijstermans et al, 2008). Although most studies support a prevalence at birth of 2% to 4% and at 3 months of age of 1% to 2%, this varies geographically, with frequency as high as 9% in some studies (Boisen et al, 2004; Virtanen and Toppaari, 2008), supporting the possibility of an increase over time. However, other data suggest that country-specific trends are not increasing (Abdullah et al, 2007; Cortes et al, 2008; Bonney et al, 2009; Wagner-Mahler et al, 2011), and overall there do not appear to be reproducible trends in prevalence (Sijstermans et al, 2008). Perinatal risk factors most consistently associated with cryptorchidism include prematurity, low birth weight or small size for gestational age, breech presentation, and maternal diabetes (Damgaard et al, 2008; Virtanen and Toppaari, 2008; Jensen et al, 2012).

The reported frequency of spontaneous testicular descent after birth varies among series, likely because of similar confounding

factors, most notably variable inclusion of boys with high scrotal testes. In several population-based prospective studies, the frequency of spontaneous descent by 3 months of age in boys identified as cryptorchid at birth was reported as 50% to 87% (Berkowitz et al, 1993; Ghirri et al, 2002; Radpour et al, 2007; Wohlfahrt-Veje et al, 2009; Wagner-Mahler et al, 2011; van der Plas et al, 2013b). In smaller cohorts, spontaneous descent occurred in significantly more Danish (68%) than Finnish (45%) boys at 3 months of age, possibly attributable to increased severity of the disease in the latter group (Suomi et al, 2006). In another series, extrascrotal testes were less likely to descend by 1 year of age (50%) than high scrotal testes defined as cryptorchid at birth (87.5%) (Acerini et al, 2009). In contrast, of 95 cryptorchid infants referred to a urology practice, spontaneous descent occurred subsequently in 16% and 0% of those presented before and after 6 months of age, respectively (Wenzler et al, 2004). The lower rate of descent in this series could be related to ascertainment age and severity of cryptorchidism in this referral population, because spontaneous descent is common before 2 months of age (Kollin et al, 2013). The long-term risk of recurrent cryptorchidism is not well defined, but in two large longitudinal series, reascent occurred in 10% and 22% of boys, in most cases between 1 and 5 years of age (Wagner-Mahler et al, 2011; Kollin et al, 2013).

Acquired Cryptorchidism

In the past, cryptorchidism was considered a congenital anomaly identifiable at birth. However, since first reported 40 years ago (Myers and Officer, 1975), **acquired cryptorchidism, or testes that are diagnosed as cryptorchid after apparent full descent at birth or in the neonatal period, is now fully accepted as a clinical entity** (Barthold and Gonzalez, 2003; Taghizadeh and Thomas, 2008; Acerini et al, 2009; Wohlfahrt-Veje et al, 2009; Hack et al, 2012). Acquired undescended testes are diagnosed at an average age of 8 to 11 years and are more commonly in a lower position, associated with a closed processus vaginalis and normal epididymis, than in cases diagnosed as congenital. The reason for a later diagnosis remains unknown; theories include presence of a fibrous remnant of the processus vaginalis that tethers or foreshortens the cord over time or mobility of the testis within an open sac (Keys and Heloury, 2012). However, it is most likely that the testis is incompletely descended from birth, because many are located in a lateral (ectopic) position within the superficial inguinal pouch (SIP) (Barthold and Gonzalez, 2003; van Brakel et al, 2011). These testes may be highly mobile and initially appear descended until somatic growth results in relative widening of the distance between testis and scrotum (Redman, 2005; Agarwal et al, 2006). Acquired cryptorchidism is reportedly more common in boys with proximal hypospadias (Tasian et al, 2010; Itesako et al, 2011) and, like the congenital form, is associated with abnormal germ cell development (Rusnack et al, 2002).

A diagnosis of acquired cryptorchidism may be more likely in boys with retractile testes, although testis retractility is common in normal populations. In a hospital-based study of unselected boys, the testis was initially suprascrotal on examination (retractile) in up to 30% of boys at 4 years and 10% of boys 4 to 12 years of age but was intrascrotal in all boys over the age of 12 (Farrington, 1968). In population-based studies of healthy boys, retractile testes were present in 11% to 15% of boys up to 11 years of age (Wohlfahrt-Veje et al, 2009; Goede et al, 2011) and 4% of 7- to 12-year-old boys (Inan et al, 2008). Both prospective and retrospective studies of the natural history of retractile testes support the concept that a subset of these becomes undescended over time. However, a selection bias exists in studies of the risk of cryptorchidism in boys with retractile testes, because those referred for follow-up by specialists are likely those with the most severe retractility. For example, Wyllie prospectively studied a cohort of 100 boys with unilateral retractile testis and identified 64 cases in which testicular position, as documented by the distance between the pubic tubercle and midtestis and/or testicular size as estimated by orchidometer, was reduced after 5 years of follow-up (Wyllie, 1984). Orchidopexy was performed in

45 of these cases, although specific documentation of testicular position and size as indications for surgery were not reported. In retrospective case series it has been reported that cryptorchidism was diagnosed in up to 7% to 32% of boys with retractile testes followed a mean of 2.2 to 3.8 years by the same observer(s) (La Scala and Ein, 2004; Agarwal et al, 2006; Stec et al, 2007). However, in a prospective study of 1072 boys, 520 of whom were followed from birth to latest follow-up at 4.5 to 10 years of age, only 2.6% developed ipsilateral cryptorchidism, although an additional 13.5% with retractile testes had other forms of cryptorchidism (contralateral or prior ipsilateral) (Wohlfahrt-Veje et al, 2009). Although these data suggest an association between retractile testes and cryptorchidism, the nature of this association may reflect either difficulty in distinguishing the two entities or the fact that significant testicular retractility is a risk factor for acquired cryptorchidism. However, the smaller volume of retractile testes suggests a common pathogenesis (Goede et al, 2011). **Careful serial physical examination is recommended to accurately determine testicular position and identify cases of acquired cryptorchidism in boys with retractile testes.**

The true prevalence of acquired cryptorchidism is incompletely defined, because longitudinal data that provide documentation of prior scrotal position are limited and address only the first few years of life. In one study, 742 infants were followed with serial examinations for 2 years after birth, with complete follow-up in 326 (Acerini et al, 2009). The prevalence of extrascrotal testes was 2.7% at birth (27% nonpalpable, surgical findings not reported), and 0.2%, 1.8%, 0.3%, and 0% of testes in the studied population became extrascrotal at 3, 12, 18, and 24 months, respectively. The number of suprascrotal testes diagnosed at birth in this series (10) was the same as the number diagnosed subsequently (10), although almost half the boys were lost to follow-up during the study. Including high scrotal testes, a total of 5.7% were identified as cryptorchid at birth and 1% to 4% rose to a high scrotal position with each follow-up visit. In another study, 1072 boys were followed with serial examinations from birth to 4.5 to 10 years of age, with complete follow-up in 500 (Wohlfahrt-Veje et al, 2009). The prevalence of congenital cryptorchidism (including high scrotal testes) was 9% at birth but dropped to 1% at 18 months, whereas 8 (1.6%) acquired cases were observed during follow-up, suggesting that the prevalence of persistent congenital and acquired forms of cryptorchidism is similar. Retrospective series also suggest that acquired cryptorchidism is common, but they cannot reliably differentiate true acquired cases from delayed referral of congenital cases (Güven and Kogan, 2008; Jensen et al, 2011; Barthold et al, 2012; Hack et al, 2012; van der Plas et al, 2013b). **Acquired cryptorchidism most likely represents a milder presentation of congenital cryptorchidism that escapes detection in infancy.**

Genetic Susceptibility

Genetic studies of cryptorchidism suggest that the disease is heritable, but that susceptibility is likely polygenic and multifactorial. Clustering of cryptorchidism has been reported in a number of families affecting multiple individuals in the same generation and variable phenotype (Minehan and Touloukian, 1974; Pardo-Mindan et al, 1975; Czeizel et al, 1981; Savion et al, 1984). Extended pedigrees were not usually examined, but autosomal dominance with reduced penetrance was most often cited as the probable mode of inheritance. Population case-control studies also support genetic contribution to the disease. Familial aggregation suggesting moderate genetic risk was reported in a large cohort study of more than 1 million male births in the Netherlands based on extensive hospital registry data (Schnack et al, 2008). Recurrence risk ratio (RR) was 10.1 in twins, 3.5 in brothers, and 2.3 in offspring and was significantly higher in maternal than in paternal half-brothers. Another population-based study in Denmark, using different methodology, identified greater concordance rates of cryptorchidism diagnosis in maternal (6%) than in paternal (3.4%) half-brothers and in dizygotic (24%) and monozygotic (27%) twins relative to brothers (9%) (Jensen et al, 2010b). However, for

surgically treated orchidopexy, presumably limiting cases to only those involving persistent cryptorchidism, concordance rates were 7.5% in brothers, 17% in dizygotic twins, and 27% in monozygotic twins. These observations suggest that environmental effects and/or maternal genetic factors contribute to the risk of cryptorchidism in Denmark. Previous smaller studies reported a 5- and 7- to 10-fold increased prevalence in fathers and brothers, respectively, of affected as compared with unaffected individuals, and some also support the possibility that maternal factor(s), or X-linked risk alleles, influence expression of the disease (Czeizel et al, 1981; Jones and Young, 1982; Elert et al, 2003; Jensen et al, 2010b; Barthold et al, 2012).

The most promising gene candidates for nonsyndromic cryptorchidism based on animal studies include *INSL3*, *RXFP2*, *HOXA10*, and *HOXA11*. However, DNA coding variants of *INSL3* and *RXFP2* are reported in only 0.6% to 1.8% and 1.6% to 2.9% of persistently cryptorchid males, respectively (Foresta et al, 2008). Notably, apparent mutations in these genes are associated with a range of phenotypes that include unilateral or bilateral and persistent or spontaneously resolving presentations, and apparently deleterious mutations may exist in normal family members, as noted for an *INSL3* mutation showing reduced receptor activation (El Houate et al, 2007). Over 1500 cryptorchidism cases have been screened for mutations in *INSL3*, but of 10 exonic variants identified in cases but not controls, few are clearly functional (Ferlin et al, 2008; Foresta et al, 2008; Bay et al, 2011). A nonsynonymous polymorphism of the *RXFP2* gene, T222P, was considered a strong etiologic candidate for cryptorchidism based on absence in normal controls and in vitro studies showing curtailed cell membrane localization and activation of the abnormal receptor (Bogatcheva et al, 2007). However, cases and controls in other European populations show a similar frequency of the T222P allele (Nutti et al, 2008; Ars et al, 2011). Although these data suggest that mutations of *INSL3* and *RXFP2* are infrequent in cases of cryptorchidism, noncoding variants that alter expression levels of the protein may exist.

Analysis of other potential candidate genes for human cryptorchidism has failed to yield consistent results. *HOXA10* mutations reported by Kolon and colleagues (1999) were not confirmed in additional series, nor were mutations identified in *HOXA11* (Bertini et al, 2004; Wang et al, 2007). Studies of polymorphic trinucleotide (CAG and GGN) repeats of *AR* in cryptorchidism also show variable results, with some studies but not others showing altered repeat length in cases (Sasagawa et al, 2000; Ferlin et al, 2005; Silva-Ramos et al, 2006; Radpour et al, 2007; Davis-Dao et al, 2012). Differences among these series may relate to small sample size (most series involve fewer than 100 cases) and heterogeneity of populations. A specific haplotype of the gene encoding ER- α (*ESR1*) did not show a consistent association with cryptorchidism in three case-control series (Yoshida et al, 2005; Galan et al, 2007; Wang et al, 2008). In a larger series of patients from Spain and Italy (373 total cases), there was no association between an *ESR1* promoter polymorphism and cryptorchidism (Lo Giacco et al, 2011). Microdeletions of the Y chromosome have also been studied in cryptorchid children and previously cryptorchid men, with no consistent association observed (Gurbuz et al, 2008; Mamoulakis et al, 2013a). A specific polymorphism of the *SF1* gene that encodes a transcription factor that regulates expression of *INSL3*, *RXFP2*, and steroidogenesis genes was associated with cryptorchidism in a single report that included 72 cryptorchid Japanese males (Wada et al, 2006). An association between aryl hydrocarbon receptor-associated genes and cryptorchidism was also noted (Qin et al, 2012). No cryptorchidism-associated variants were identified in the sex hormone-binding globulin gene (*SHBG*) or in genes associated with hypogonadotropic hypogonadism (Laitinen et al, 2011; Mamoulakis et al, 2013b). Reliability of the results of many of these studies is limited because of insufficient sample size and/or lack of replication in other population groups.

Results of unbiased genome-wide studies of cryptorchidism are also limited. In a whole-genome analysis of copy number variation in boys with genital defects (Tannour-Louet et al, 2010), potential loci associated with cryptorchidism were identified in the 10p14 and Xq28 regions. A genome-wide association study (GWAS) of 488

men with at least one of the four phenotypes comprising the so-called testicular dysgenesis syndrome (TDS) (Sharpe and Skakkebaek, 2008) including infertility, cryptorchidism ($n = 138$), hypospadias, and/or testicular germ cell tumor (TGCT) (Dalgaard et al, 2012) was reported. Although the authors did not identify a locus associated with cryptorchidism that passed the stringent genome-wide significance threshold, they used a systems biology approach to identify less significant signals of potential importance. In doing so, they identified the transforming growth factor (TGF) receptor III (*TGFBR3*) gene, which is also associated with transient Leydig cell dysgenesis in knockout mice (Sarraj et al, 2010), as a potential locus associated with cryptorchidism and TGCT in both discovery and replication cohorts. *TGFBR3* protein is expressed in fetal Leydig cells (Dalgaard et al, 2012) and interacts with TGF- β 2 (Bilandzic and Stenvers, 2011). Incomplete testicular descent was reported in *Tgfb2*^{-/-} mice (Sanford et al, 1997) but not in *Tgfb3*^{-/-} mice, which rarely survive past birth.

In a larger GWAS of 844 boys with nonsyndromic cryptorchidism, signals showing suggestive association included those in *TGFBR3* and in cytoskeleton-related genes, but those reaching genome-wide significance were rare, occurred only in subphenotype analysis, and were not replicated in an independent population, suggesting significant genetic heterogeneity (Barthold et al, 2015a, 2015b).

In summary, studies to date are consistent with the assumption that cryptorchidism is a genetically complex disease, likely associated with multiple susceptibility loci. Failure to identify consistent loci associated with cryptorchidism is likely related to methodology, particularly insufficient sample size, phenotypic variability, and other confounding factors such as environmental influences. **Therefore, although multiple genetic variants likely contribute to the risk of nonsyndromic cryptorchidism, most remain unknown at this time.**

Environmental Risk Factors

Population-based studies suggest that the maternal environment may contribute to the risk of cryptorchidism, but it remains unclear if risk is related to maternal exposures, characteristics, or lifestyle. Maternal alcohol consumption or binge drinking was associated with cryptorchidism in some studies but not others (Thorup et al, 2006; Damgaard et al, 2007; Jensen et al, 2007; Mongraw-Chaffin et al, 2008; Strandberg-Larsen et al, 2009). A review of data for maternal smoking confirms inconsistent results but suggests that a small-to-moderate increased risk for cryptorchidism is present in offspring (Hakonsen et al, 2014). Several series have suggested increased risk with maternal use of acetaminophen or more than one analgesic in midpregnancy or earlier (Jensen et al, 2010a; Kristensen et al, 2011; Snijder et al, 2012). Parental occupation is not consistently associated with cryptorchidism in offspring, although some data suggest increased risk in horticulture-related professions (Weidner et al, 1998; Pierik et al, 2004; Andersen et al, 2008; Gabel et al, 2011; Morales-Suarez-Varela et al, 2011; Jørgensen et al, 2013, 2014). Although risk factors for acquired cryptorchidism have not been specifically addressed, a single study addressing this issue identified reduced breastfeeding and increased use of soy formula as variables associated with first diagnosis of cryptorchidism at an older age (Barthold et al, 2012).

Testicular dysgenesis syndrome is the term used to describe a potentially related constellation of reproductive abnormalities including cryptorchidism, hypospadias, infertility, and TGCT (Sharpe and Skakkebaek, 2008). The proposed cause is a deficiency in fetal androgen production resulting from exposure to endocrine-disrupting chemicals (EDCs). The concern for a link between EDCs and cryptorchidism arose because of a reported increased risk of cryptorchidism after maternal exposure to diethylstilbestrol (DES) (Gill et al, 1979). In a large cohort study of 1197 men previously exposed to DES and 1038 unexposed men, the RR of cryptorchidism was 1.9 (95% confidence interval [CI] 1.1 to 3.4) overall. When data were subdivided based on gestational age less than 11 weeks and exposure of 5 g or more, the RRs were 2.9 (95% CI

1.6 to 5.2) and 3.2 (95% CI 1.7 to 6.0), showing that early and significant exposure present the clearest risks (Palmer et al, 2009). Data supporting a link between EDCs other than DES and cryptorchidism are less clear (reviewed in Virtanen and Adamsson, 2012). Animal models suggest a relationship between prenatal exposure to antiandrogenic EDCs and risk of cryptorchidism and other reproductive end points, and suggest additive effects of chemical mixtures, although levels of exposure are much higher than applicable clinically (Rider et al, 2009) and concerns exist about the applicability of EDC animal models to humans (Habert et al, 2014). Notably, recent evidence suggests that species-specific, differential sensitivity to EDCs exists. Human testes appear insensitive to inhibition of steroidogenesis by phthalates or DES, but more sensitive to the inhibitory effects of bisphenol A (Lambrot et al, 2009; Heger et al, 2012; Mitchell et al, 2012; N'Tumba-Byn et al, 2012). In addition, measured levels of antiandrogenic and/or estrogenic EDCs in placenta, breast milk, or cord blood, including pesticides, polychlorinated biphenyls (PCBs), dioxins, perfluorinated compounds, flame retardants (polybrominated diphenyl ethers [PBDEs]), and organotin were not consistently higher in association with affected pregnancies (Damgaard et al, 2006; Main et al, 2007; Cook et al, 2011; Fenichel et al, 2012; Trabert et al, 2012; Virtanen et al, 2012; Rantakokko et al, 2013; Vesterholm Jensen et al, 2014). Consistent with data showing lack of inhibition of human fetal testicular steroidogenesis by phthalates, levels of individual phthalate metabolites did not show consistent correlation with occurrence of cryptorchidism or hormone levels in affected boys (Main et al, 2006a).

Because EDC exposure is difficult to measure at relevant fetal time points, an alternative approach that has been used to potentially link exposures that could inhibit virilization with reproductive outcomes is measurement of anogenital distance (AGD), or perineal length from the posterior margin of the scrotum to the anal verge. AGD is sexually dimorphic and correlated with newborn body weight (Sathyanarayana et al, 2010). Reduced AGD was correlated with phthalate exposure, AR CAG repeat length, cryptorchidism, hypospadias, and variants in genes linked to reproductive anomalies, including *ESR1* (Sathyanarayana et al, 2012; Dean and Sharpe, 2013; Eisenberg et al, 2013; Jain and Singal, 2013; Thankamony et al, 2014). These observations warrant further investigation into the association of fetal androgen action and cryptorchidism. However, the existence of TDS as an environmentally induced syndrome remains provisional, as the available evidence does not strongly support direct links between EDC exposure and their occurrence in humans (Akre and Richiardi, 2009; Thorup et al, 2010; Habert et al, 2014). A causal association between single chemicals or classes of EDCs and risk of cryptorchidism may be difficult to demonstrate in view of the presumed heterogeneity of susceptibility to the disease, but the wide variety of EDCs to which humans are exposed may allow for synergistic effects that are difficult to measure. **At present, epidemiologic data suggest potential associations in selected populations but do not strongly support environmental chemicals as a cause of increased susceptibility to cryptorchidism in the human population.**

Testicular hormones are required for testicular descent; therefore defective hormone production and/or action may contribute to the pathogenesis of cryptorchidism and may manifest during postnatal activation of the HPG axis (see Fig. 148-1). Prospective studies of varying size and quality are available that report postnatal hormone levels in cryptorchidism, and although some data suggest that the HPG axis is abnormal, results are conflicting and baseline levels do not directly reflect the status of germ cell development. In the first reported series of cryptorchid and control boys undergoing hormonal evaluation in the first few months of life, serum testosterone was lower in 7 of 17 (41%) persistently cryptorchid boys but comparable to control levels in 4 of 25 boys with spontaneous testicular descent (Gendrel et al, 1978). Subsequent studies have shown reduced hormone levels in some series (Facchinetti et al, 1983; Raivio et al, 2003; Pierik et al, 2009) but not others (De Muinck Keizer-Schrama et al, 1988; Barthold et al, 2004). In a larger series, Suomi and colleagues showed geographic differences in serum

inhibin B and follicle-stimulating hormone (FSH) levels but no differences in testosterone levels in cryptorchid infants from Finland (88 boys, 36% spontaneous descent) and Denmark (34 boys, 68% spontaneous descent) as compared with 300 and 399 control boys, respectively (Suomi et al, 2006). In a related cohort, INSL3 levels were reduced in cord blood but not in serum obtained at 3 months of age in persistently cryptorchid boys (Bay et al, 2007). These studies, however, do suggest that LH-to-testosterone and LH-to-INSL3 ratios are increased in boys with cryptorchidism, suggesting that reduced Leydig cell function may lead to upregulation of LH (Suomi et al, 2006; Bay et al, 2007). In the largest series to date of 225 boys with congenital cryptorchidism in whom LH, FSH, testosterone, and inhibin B were measured at 0 to 3 weeks, 2 months, and 6 months of age ($n \geq 57$ per time point), hormone levels were not significantly different among unilateral, bilateral, and spontaneously resolving cryptorchidism, and did not correlate with spermatogenesis (Kollin et al, 2012).

Other studies of Sertoli-germ cell function as determined by serum assays in boys with cryptorchidism suggest that abnormalities may exist, but data are inconsistent among studies. In a longitudinal study of 27 boys (mean age 4.8 years) undergoing orchidopexy, an increase in serum inhibin B was identified in a majority of patients 6 months postoperatively (Irkilata et al, 2004). In 69 older boys undergoing bilateral orchidopexy (median age 2 years), the majority (75%) with congenital cryptorchidism, FSH levels were increased in 17 (25%), inhibin B levels were decreased in 9 (13%), and germ cell counts were not closely correlated with hormone levels (Thorup et al, 2012). Elevated FSH levels normalized in 14 (82%) of patients postoperatively. In another series of 62 boys (mean age 7.7 years), no differences were identified in inhibin B levels or in LH, FSH, or testosterone levels before or after hCG stimulation (Christiansen et al, 2002). AMH levels were measured in three prospective studies of boys with cryptorchidism as compared with age-matched controls. Lower AMH levels were seen in a subset of patients younger than 8 years included in a study of 104 cryptorchid boys (mean age 4 to 5 years) (Yamanaka et al, 1991) and also in a case-control study of 12-month-old boys ($n = 20$ per group) in whom levels did not change after orchidopexy (Demircan et al, 2006). However, in another study, no differences in AMH levels were seen in 1- to 6-month-old cryptorchid ($n = 43$) versus control ($n = 113$) boys (Pierik et al, 2009).

These studies suggest that some cryptorchid boys have measurable abnormalities in pituitary and/or gonadal hormone secretion during infancy in the absence of generalized, persistent endocrine dysfunction. Inconsistent findings among studies are likely based on timing and type of assays, sample size, and heterogeneity based on age, severity, genetic background, and/or other interindividual differences. No hormonal studies to date have been shown to closely predict germ cell numbers or long-term testicular function in boys with cryptorchidism. Because multiple genetic and environmental factors likely contribute to cryptorchidism, identification of risk factors is difficult in case-control studies.

Syndromic Cryptorchidism

Undescended testes are frequently present in diseases associated with reduced androgen production and/or action, such as androgen biosynthetic defects, androgen insensitivity, Leydig cell agenesis, and gonadotropin deficiency disorders (Barthold et al, 2000; Foresta et al, 2008). These conditions are associated with generalized failure of masculinization, are considered disorders of sexual differentiation (DSD), and are not reviewed here. Persistent müllerian duct syndrome, a DSD resulting from defective AMH signaling, is also associated with cryptorchidism or transverse testicular ectopia (Josso et al, 2006). Gubernacular defects that are observed in these patients may be caused by hindrance of descent by retained müllerian ducts (Barteczko and Jacob, 2000) and/or via loss of direct proliferative effects of AMH on the gubernaculum (Kubota et al, 2002). The frequency of Klinefelter syndrome (47,XXY) is below 2% in large series of primarily nonsyndromic cryptorchidism but is higher when other anomalies, particularly hypospadias, are

present (Sasagawa et al, 1996; Moreno-Garcia and Miranda, 2002; Ferlin et al, 2008). Over half of prepubertal patients with Klinefelter syndrome have cryptorchidism (Pacenza et al, 2012). Other genomic rearrangements and trisomies, including Down syndrome (trisomy 21), are associated with cryptorchidism (Hadziselimovic, 1983).

Certain anomalies are associated with increased risk of cryptorchidism, many related to musculoskeletal, central nervous system (CNS), or abdominal wall or gastrointestinal defects. These include all cases of classic prune-belly (triad or Eagle-Barrett) syndrome, 80% of spigelian hernia (Durham and Ricketts, 2006; Bilici et al, 2012; Balsara et al, 2014), 41% to 54% of cerebral palsy (Rundle et al, 1982; Cortada and Kousseff, 1984), 38% of arthrogryposis (Fallat et al, 1991), 15% of myelomeningocele (Ferrara et al, 1998), 16% to 33% of omphalocele, 5% to 15% of gastroschisis (Kaplan et al, 1986; Koivusalo et al, 1998; Yardley et al, 2012), 19% of imperforate anus (Cortes et al, 1995b), 12% to 16% of posterior urethral valve (Krueger et al, 1980; Heikkila et al, 2008), and 6% of umbilical hernia (Kaplan et al, 1986) patients. Multisystem anomalies are often associated with omphalocele (80%) and prune-belly syndrome (45%), suggesting a syndromic cause (Loder et al, 1992; Koivusalo et al, 1998). Depue also reported a significant association of cryptorchidism with CNS dysfunction, particularly cerebral palsy (RR = 34), low IQ (RR = 2.7), and hypotonia (RR = 3.6) (Depue, 1988). Cortes and colleagues reported associations between renal and T10 to S5 spinal anomalies and cryptorchidism, with the affected testis on the same side as the renal anomaly in 90% of cases (Cortes et al, 1998). In addition, syndromic cryptorchidism, especially with CNS malformations, is more commonly bilateral (Cendron et al, 1993; Cortes et al, 1995b). These data support common origins of cryptorchidism and anomalies of urogenital ridge, abdominal wall, lumbosacral spine, and CNS development.

The occurrence of cryptorchidism with other nongenital anomalies may complicate and/or alter the timing of treatment. For example, spigelian hernia may be difficult to diagnose, and associated absence of the gubernaculum and inguinal canal may complicate orchidopexy (Bilici et al, 2012; Balsara et al, 2014). Spontaneous testicular descent is reported in 50% to 55% of gastroschisis patients (Hill and Durham, 2011; Yardley et al, 2012) suggesting that observation is warranted.

DIAGNOSIS

To best determine testicular position, boys should be examined in the supine and, if possible, upright cross-legged and standing positions. Abduction of the thighs contributes to inhibition of the cremasteric reflex, which is elevation of the testis that is elicited by scratching the inner thigh. The examination should include documentation of testicular palpability, position, mobility, size, and possible associated findings such as hernia, hydrocele, penile size, and urethral meatus position. Patient distraction, a warm room and hands, use of liquid soap on the examiner's hands, and repeated examinations also help to localize the testis and to limit cremaster muscle activity and resultant difficulty in determining testicular position. Sustained gentle traction on the cord can help to inhibit the cremaster reflex and allow a retractile testis to remain at least temporarily in stable scrotal position. Scrotal asymmetry can be a useful clinical sign because it is commonly present in boys with unilateral cryptorchidism (Fig. 148-5) (Snodgrass et al, 2011).

In large clinical series, the majority (75% to 80%) of undescended testes are palpable and 60% to 70% are unilateral; involvement of the right side is more common overall but less frequent in series of nonpalpable testes (Hadziselimovic, 1983; Cendron et al, 1993; Cortes et al, 2001; Giannopoulos et al, 2001). Position of undescended testes varies markedly with the population studied, which may in part be the result of different classification techniques. In a meta-analysis of surgical patients, testes were abdominal in 34%, near the internal ring ("peeping") in 12%, canalicular in 27%, and beyond the external ring in 27% (Docimo, 1995), whereas in large single-institution series testes were abdominal in 3% to 10%

Figure 148-5. Scrotal asymmetry in a boy with unilateral left cryptorchidism.

of total cases, canalicular in 16% to 27%, and distal to the external ring in the majority (Hadziselimovic, 1983; Moul and Belman, 1988; Cendron et al, 1993; Kraft et al, 2011). In a multi-institutional review of almost 40,000 European cryptorchid boys, 8% of testes were abdominal, 63% canalicular, 24% prescrotal, and 11% in the SIP or ectopic (Hadziselimovic, 1983). Moul and Belman classified all subinguinal testes with a lateral gubernacular attachment as ectopic (66% of their total cases).

Associated genital findings may warrant additional diagnostic studies that are best completed in the neonatal period. If neither testis is palpable, particularly if penile development is abnormal, karyotype and hormonal analyses are performed urgently to rule out congenital adrenal hyperplasia and obviate the potential adverse effects of undiagnosed salt wasting. Routine circumcision should be delayed until evaluation confirms a genetically normal male. Hypospadias is associated with cryptorchidism in 12% to 24% of cases (Cendron et al, 1993; Moreno-Garcia and Miranda, 2002; Cox et al, 2008). If proximal hypospadias is present, chromosomal analysis is warranted because the frequency of abnormalities is high (32% to 47%) (Cox et al, 2008; Sekaran et al, 2013). Micropenis was reported in 46% of boys with anorchia caused by bilateral vanishing testes (Zenaty et al, 2006) (also called *testicular regression syndrome*), and small penile size in association with cryptorchidism is also observed in cases of hypogonadotropic hypogonadism. In these patients, measurement of testosterone, LH, and FSH levels in the first few months of life during the window of opportunity afforded by the physiologic activation of the HPG axis can facilitate early identification of hormone deficiency or anorchia (Grumbach, 2005).

Palpable Testes

Undescended testes may be located along the line of normal descent between the abdomen and scrotum or in an ectopic position that is most commonly the SIP (anterior to the rectus abdominus muscle) or, more rarely, in a perirenal, prepubic, femoral, peripenile, perineal, or contralateral scrotal position (Fig. 148-6). Careful

examination of these areas is needed to correctly classify a testis as palpable or nonpalpable, a critical step that influences further diagnosis and treatment (Fig. 148-7). Every effort should be made by the examiner to determine the lowest position the testis may attain. Manual downward pressure with one hand along the ipsilateral inguinal canal from the anterior iliac spine to the scrotum and palpation with the opposite hand helps to identify the lowest position of a palpable testis.

Difficulty in the clinical classification of cryptorchidism when the testis is palpable is related to both documentation of testicular

position and differentiation of truly undescended from retractile testes, complicated by the fact that these entities may coexist. The gold standard for diagnosis remains careful examination of a child in several positions and confirmation of incomplete descent of the testis to a dependent scrotal position after induction of anesthesia. Prospective studies of intraobserver and interobserver variation show major differences in documentation of testicular position among examiners (Wit et al, 1987; Olsen, 1989). Olsen noted complete agreement between two examiners on scaled measures of testicular position and mobility in only 5 (13.5%, 95% CI 4.5% to 28.8%) of 37 boys. Cendron and colleagues reported that preoperative testicular position correlates poorly with intraoperative findings (Cendron et al, 1993). Variation in observed testicular position preoperatively and postoperatively may influence assessment of prognosis and outcome in boys with cryptorchidism.

Figure 148-6. Positions of the ectopic testis. The ectopic testis can be identified in various positions, as shown. The most common location is the superficial inguinal pouch.

Nonpalpable Testes

When a testis is nonpalpable, possible clinical findings at surgery include (1) abdominal or transinguinal “peeping” location (25% to 50%) (Fig. 148-8; also see Fig. 148-6), (2) complete atrophy (vanishing testis, 15% to 40%) (Fig. 148-9), and (3) extra-abdominal location but nonpalpable testis because of body habitus, testicular size, and/or limited cooperation of the patient (10% to 30%) (Cendron et al, 1993; Cisek et al, 1998; Kirsch et al, 1998; Radmayr et al, 2003; Patil et al, 2005). If both testes are nonpalpable and not distal to the internal inguinal ring in a genetic male, at least 95% are abdominal, with cases of bilateral vanishing testis occurring rarely (Cendron et al, 1993; Moore et al, 1994). If neither vas nor spermatic artery is found at the time of laparoscopy, laparoscopic or surgical dissection of the perivesical area and retroperitoneum up to the level of the kidney is required for exclusion of the presence of a testis, because true agenesis is extremely rare. Perirenal or other abdominal testes may be associated with

multicystic dysplastic or absent ipsilateral kidneys and/or nonunion of the testis and epididymis (Zaccara et al, 2004; Foley et al, 2005; Kim et al, 2005).

The cause of vanishing testis is not known but is thought to represent spermatic cord torsion or vascular accident occurring after completion of genital masculinization but before fixation of the testis in the scrotum. Evidence supporting this includes the presence of hemosiderin in remnant testicular nubbins excised at surgery (Turek et al, 1994) and reported cases of contralateral postnatal torsion (Gong et al, 1996). An enlarged contralateral testis (Huff et al, 1992) and absence of palpable intrascrotal appendage tissue (processus vaginalis, wolffian structures, or gubernaculum) are highly predictive of a vanishing testis (Mesrobian et al, 2002). Diagnosis of a vanishing testis requires documentation of blind-ending spermatic vessels in the abdomen, inguinal canal, or scrotum.

Endocrine evaluation in cases of suspected bilateral vanishing testes (anorchia) shows elevated basal serum gonadotropin levels and no response to hCG stimulation; however, gonadotropins may

be unexpectedly low in midchildhood in boys who are also unresponsive to hCG (Lustig et al, 1987; Lee, 2000). Because hCG stimulation testing is not well standardized and has the potential for side effects and inaccuracy, it is no longer the procedure of choice for documentation of anorchia (Kolon et al, 2014). In most cases, laparoscopic or surgical abdominal exploration is performed, although hormone testing can also be useful and may be sufficient for the diagnosis of anorchia. In the absence of testicular tissue, FSH and LH levels are higher than normal in early infancy and FSH level is reportedly always higher than 2 IU/L before age 6 (Grinspon et al, 2012). Very low or undetectable AMH and inhibin B levels are also reported as useful adjuncts in the diagnosis of anorchia (Grumbach, 2005; Brauner et al, 2011; Thorup et al, 2011b).

Inguinoscrotal ultrasonography and magnetic resonance imaging (MRI) are not usually helpful and are not recommended in the evaluation and management of a nonpalpable testis (Elder, 2002; Tasian et al, 2011) (Kolon et al, 2014). Overall, the sensitivity and specificity of ultrasound in localizing the nonpalpable testis are 45% and 78%, respectively (Tasian and Copp, 2011). In a recent meta-analysis, the sensitivity and specificity of MRI in identifying cryptorchid testes were 65% and 100%, respectively, and were higher for inguinal than for abdominal testes (Krishnaswami et al, 2013). No imaging modality is reliable for diagnosing vanishing testes. Some authors advocate very selective use of imaging if recommended by the managing surgical specialist after referral; in this situation the sensitivity of ultrasonography in identifying inguinal testes is reported to be as high as 95% to 97%, and abdominal testes are also seen in some cases (Cain et al, 1996; Nijs et al, 2007), but examination under anesthesia is likely to provide the same information (Tasian et al, 2011). Similarly, although MRI can be useful in some cases to identify nonpalpable abdominal testes, its accuracy is variable and the procedure requires sedation in younger children and is unlikely to change the management approach (Yeung et al, 1999; Siemer et al, 2000). The superior accuracy of magnetic resonance angiography (MRA) in localizing and differentiating viable from vanished testes (96% of 23 nonpalpable testes in 21 boys, mean age 2.5 years) was not replicated in a study of younger boys (57% of 29 testes in 26 boys, mean age 13 months) (Yeung et al, 1999; Desireddi et al, 2008). One indication for MRI may be identification of an ectopic abdominal testis not localized by laparoscopy. Imaging is not indicated for diagnosis of the nonpalpable testis, because it has limited accuracy and does not obviate the need for definitive surgical intervention.

Diagnostic laparoscopy, followed by laparoscopic orchidopexy if an abdominal testis is present, has become the preferred approach to the nonpalpable testis for many clinicians. Laparoscopy is preceded by an examination under anesthesia, which may be a useful adjunct that helps to define the appropriate course of action. Although laparoscopy does not always provide a direct diagnosis, in many cases it either provides visualization of the testis or guidance for the surgeon's next steps. Important laparoscopic observations include the size and position of the spermatic vessels and vas; testicular size, quality, and position if visible; and patency of the internal inguinal ring. The combination of a closed internal ring and a blind-ending spermatic artery and vas confirms an abdominal vanishing testis (see Fig. 148-9), whereas a hernia is frequently but not always associated with a viable abdominal or distal testis (Elder, 1994; Moore et al, 1994). An atretic spermatic cord coursing through a closed inguinal ring is suggestive of a distal vanishing testis, but this finding may be subjective and, conversely, normal-appearing vessels may be associated with both viable and vanishing testes (Zaccara et al, 2004). Moreover, the laparoscopic view may suggest abdominal blind-ending vessels despite a testis being present distally or in an ectopic abdominal position (Zaccara et al, 2004; Kim et al, 2005; Ellsworth and Cheuck, 2009). Therefore if laparoscopy does not unequivocally localize the testis or blind-ending spermatic artery, additional surgical exploration is needed for definitive diagnosis. This may be performed laparoscopically after the placement of additional working ports.

The need for excision and contralateral scrotal orchidopexy in vanishing testis cases remains controversial. Germ cells and/or

tubules are consistently present in 5% to 15% of excised testicular remnants (Moore et al, 1994; Tennenbaum et al, 1994; Turek et al, 1994; Cortes et al, 1995a; De Luna et al, 2003; Renzulli et al, 2005; Bader et al, 2011), but the risk of malignancy is unknown. A single case of carcinoma in situ (CIS) was reported by Rozanski and colleagues in a testicular remnant (Rozanski et al, 1996). Excision is appropriate when the spermatic vessels traverse the internal inguinal ring, to provide confirmation that no viable (or atrophic) testis is present, because the laparoscopic appearance of the spermatic vessels and processus vaginalis may be deceiving and may not reliably exclude the presence of an inguinal testis (Ellsworth and Cheuck, 2009). Vanishing testes are often in or near the scrotum; therefore, initial scrotal exploration should be considered when a palpable scrotal nubbin and contralateral testicular hypertrophy (testicular length ≥ 1.8 cm) are present (Belman and Rushton, 2003; Snodgrass et al, 2007). However, a trans-scrotal search will be time-consuming and unproductive when a vanishing testis is intra-abdominal. Moreover, in cases of testicular-epididymal dissociation, a scrotal nubbin may actually be the epididymis instead of a vanishing testis; a laparoscopic approach facilitates more accurate diagnosis and subsequent management of such cases (Wolffenbuttel et al, 2000; De Luna et al, 2003). Laparoscopy is the procedure of choice to confirm or exclude the presence of a viable or remnant abdominal testis, unless a prominent scrotal nubbin is palpable with other clinical signs of monorchism.

Contralateral fixation of a solitary testis in cases of monorchism is advocated by some but not universally supported. The possibility that prenatal torsion is the cause of vanishing testis (Gong et al, 1996) does not imply that the contralateral testis is likely to undergo a similar fate after the postnatal period. However, some surgeons empirically recommend contralateral fixation to eliminate the risk of such a devastating complication (Rozanski et al, 1996) and/or because a contralateral bell-clapper deformity (incomplete testicular fixation to the tunica vaginalis) may be present (Bellinger, 1985; Al-Zahem and Shun, 2006). However, review of the anatomy of the tunica vaginalis contralateral to vanishing testes suggests that the bell-clapper anomaly is rare and the risk of torsion of the solitary testis in these cases is minimal (Martin and Rushton, 2014).

Associated Pathology

Testicular Maldevelopment

Many observational studies of the histologic development of prepubertal cryptorchid testes have been published. Over 40 years ago, Mancini and colleagues systematically reported germ cell counts and related arrested development of spermatogonia with progressive loss in cryptorchid testes (Mancini et al, 1965). Subsequently, several large series, some with additional normal autopsy (Hedinger, 1982) or affected control (hernia, hydrocele) (Hadziselimovic et al, 1986) data and others that refer to these established age-dependent norms (Schindler et al, 1987; Gracia et al, 1995; McAleer et al, 1995; Cortes et al, 2001; Huff et al, 2001), have provided mainly consistent findings in cryptorchid boys. These data show that the number of spermatogonia (germ cells) per tubule is reduced after infancy and fails to increase normally with age in cryptorchid and to a lesser degree in contralateral scrotal testes. The frequency of abnormal histology in the contralateral testis varies among studies, ranging from 22% to 95%, and is likely reflective of differences in patient populations, use of control data, and methodology. Moreover, variability within and among biopsies from single testes has been reported (Hedinger, 1982; Schindler et al, 1987). However, these data provide strong evidence that abnormal germ cell development is often present after early infancy in cryptorchid testes. The degree of pathology was similar in true ectopic, SIP, and ascending testes (Herzog et al, 1992; Hutcheson et al, 2000b; Rusnack et al, 2002) and was more severe in limited samples from patients with myelomeningocele, posterior urethral valves, and prune-belly syndrome (Orvis et al, 1988; Patel et al, 2008). Findings are similar in boys with secondary cryptorchidism after hernia repair, suggesting that these may in fact be cases of primary

cryptorchidism (Fenig et al, 2001). In other studies, higher germ cell counts were correlated with reduced age-dependent interstitial fibrosis (Suskind et al, 2008), lower age at surgery, and increased likelihood of testicular palpability (Tasian et al, 2009; Kraft et al, 2011). In a series of 723 boys with cryptorchidism (14% bilateral), testicular volume did not predict germ cell count (Noh et al, 2000), but in a subsequent series of 1326 boys with unilateral cryptorchidism from the same institution, testis volume was positively correlated with germ cell counts in both undescended and contralateral descended testes (Kraft et al, 2011).

Detailed studies of peritubular myoid and Sertoli cells in cryptorchidism are limited, but their abnormal development or function may contribute to the observed germ cell abnormalities. The available data suggest disruption of prepubertal Sertoli cell morphology, failure of maturation at puberty, and evidence for reduced number after 4 months of age in cryptorchid testes (Lackgren and Ploen, 1984; Rune et al, 1992; Regadera et al, 2001; Zivkovic and Hadziselimovic, 2009). Reduced expression of type IV collagen, a product of both Sertoli and myoid cells that may function in cell-cell communication, was reduced in basement membranes of undescended and contralaterally descended testes (Santamaria et al, 1990).

Impaired transformation of gonocytes to spermatogonia is reported in cryptorchid testes and may help define fertility potential. Although the ratio of gonocytes to spermatogonia appears to be normal in cryptorchid testes at about 1.5 months of age, delays in the disappearance of gonocytes and in the appearance of adult dark (Ad) spermatogonia occur in the undescended as compared with the contralateral descended testis (Hadziselimovic et al, 1986; Huff et al, 2001). As noted for germ cell counts, the reported percentage of cryptorchid testes lacking Ad spermatogonia varies widely from 17% to 85% (Zivkovic et al, 2009; Thorup et al, 2013). Ad spermatogonial number may also be reduced in the contralateral testis of boys with unilateral cryptorchidism (Kraft et al, 2011). In addition, the appearance of primary spermatocytes at age 4 to 5 years is delayed in cryptorchid testes (Huff et al, 1989).

Kollin and colleagues studied testicular growth in undescended and scrotal testes and measured the effect in orchidopexy on testicular size using serial ultrasonography in prospective randomized studies of congenital cryptorchidism (Kollin et al, 2006, 2007, 2012, 2013). They showed that the undescended testis is smaller at birth and grows less well than the scrotal testis, even if spontaneous descent occurs. Postoperative testicular growth was superior in boys who underwent orchidopexy at age 9 months as compared with those randomized to surgery at age 3 years. Biopsies at the time of orchidopexy in these patients showed marked reductions in germ cell number and a less prominent reduction in Sertoli cells when orchidopexy was delayed until age 3. In these studies, inhibin B levels correlated with testicular volume, as reported previously for neonates with normal testes, where inhibin B levels were interpreted to primarily reflect differences in Sertoli cell number (Main et al, 2006b; Sharpe, 2006). These well-conducted prospective studies provide strong support for the concept that cryptorchidism is associated with both primary and secondary effects on testicular development, and that the extrascrotal position of the testis may have adverse effects even in infancy.

Anomalies of the Epididymis, Processus Vaginalis, and Gubernaculum

Attachment of the epididymis to the testis may be abnormal in cryptorchid boys (Marshall and Shermeta, 1979), but the reported frequency varies widely from 16% to 75% (Heath et al, 1984; Merksz and Toth, 1987; Gill et al, 1989; Mollaeian et al, 1994; Kraft et al, 2011), most likely because characterization of this anomaly may be subjective. Anatomic findings in decreasing order of frequency include partial or complete nonfusion between the caput and/or cauda epididymis and the testis, epididymal elongation and/or looping, and atresia (Fig. 148-10). The occurrence of epididymal anomalies correlates with both the severity of cryptorchidism and the degree of closure of the processus vaginalis (Elder,

Figure 148-10. Epididymal anomalies. A, Normal epididymis. B, Looped epididymis. C, Malunion of the tail of the epididymis.

1992; Barthold and Redman, 1996). Epididymal anomalies were more common in congenital (37% to 60%) than acquired (11% to 31%) cryptorchidism (Barthold et al, 2012; van Brakel et al, 2012). Complete epididymal detachment or nonunion between the testis and epididymis and vas is rare and more likely to be associated with abdominal testes (Foley et al, 2005; Wakeman and Warner, 2010; Karaman et al, 2011; Sharma and Sen, 2013) but did not correlate with testicular histology (Kraft et al, 2011). However, the degree to which these anomalies alter sperm transport, if at all, and potentially contribute to subfertility in males with a history of cryptorchidism remains undefined.

Failure of closure of the processus vaginalis (inguinal hernia) and abnormal attachment of the gubernacular remnant are common in association with cryptorchidism. In their study of 759 patients, Cendron and colleagues identified a persistently patent processus vaginalis ipsilateral to 87% of unilateral and 71% of bilateral undescended testes. Specific notation of the gubernacular position available from this and another large study indicates aberrant attachment lateral to the scrotum in 66% to 75% of cases (Moul and Belman, 1988; Cendron et al, 1993). The processus is patent in 45% to 50% of boys with ascending testes, possibly related to older patient age and/or reduced severity of cryptorchidism in this group (Barthold and Gonzalez, 2003; Barthold et al, 2012; van Brakel et al, 2012). Inguinal hernia is also more common in family members of boys with cryptorchidism (Barthold et al, 2012). **Anomalies of the tunica and processus vaginalis in cryptorchidism predispose to development of testicular torsion or clinical hernia, respectively, in rare cases.** Torsion of an undescended testis can occur at any age (reviewed by Zilberman et al, 2006) and may be confused with an incarcerated inguinal hernia. The risk of torsion is higher in undescended than in scrotal testes and may be particularly high in

children with neuromuscular diseases such as cerebral palsy. Delay in diagnosis is common, and a high index of suspicion is needed to reduce the high risk of testicular loss. Of particular concern is the potential risk for delayed diagnosis with resultant testicular necrosis during the postnatal period when infants are observed for spontaneous testicular descent (Singal et al, 2013).

Other Testicular Anomalies Associated with Cryptorchidism

Several rare anomalies of testicular development associated with cryptorchidism, each with 100 to 150 reported cases in the literature, include polyorchidism, splenogonadal fusion, and transverse testicular ectopia. Because abdominal cryptorchidism commonly occurs in these cases, laparoscopy is useful in both diagnosis and treatment.

Polyorchidism is the presence of a supernumerary testis that is more commonly unilateral and on the left side, with rare cases of bilateral duplication or triplication reported in a comprehensive meta-analysis of the pediatric and adult literature (Bergholz and Wenke, 2009). The cause is unknown, but most authors speculate that this anomaly is related to duplication or division of the genital ridge with or without the wolffian duct as illustrated by Danrad and colleagues (2004). Testes are reported to be scrotal, inguinal, and abdominal in 75%, 20%, and 5% of cases, respectively (Kumar et al, 2008). Affected individuals are frequently asymptomatic, and the polyorchidism is identified at the time of orchidopexy or hernia repair, although a scrotal or inguinal mass and pain with or without torsion may occur and persistent müllerian remnants may coexist. Various classification schemes have been proposed, with a recent trend toward categorizing testes based on epididymal and vasal configuration (Bergholz et al, 2007; Khedis et al, 2008; Kumar et al,

2008). Kumar and colleagues suggest a classification that differentiates between testes that are drained by a vas deferens (type A1—separate epididymis and vas; type A2—separate epididymis; type A3—shared epididymis and vas) and those with no vasal drainage (type B1—epididymis present; type B2—no epididymis or vas). This classification can aid in management decisions that should be based not only on the anatomy of the accessory ducts but also the position, size, and attachments of the testis. Observation and periodic self-examination without surgery should be considered for sonographically normal scrotal testes and orchidopexy for testes that are undescended but with intact ductal drainage (Spranger et al, 2002; Bergholz et al, 2007; Khedis et al, 2008). Occasional cases of testicular tumor have been reported in supernumerary testes, but it is unclear if this is a risk related to polyorchidism per se or to associated cryptorchidism or persistent müllerian duct syndrome (Spranger et al, 2002; Ghose et al, 2007). Testicular torsion may also occur (Arlen et al, 2014).

Splenogonadal fusion is a defect characterized by continuous or discontinuous fibrous union between splenic tissue and the gonad, a condition much more commonly recognized in males (Khairat and Ismail, 2005) (Fig. 148-11). In the continuous form (55%) a cord connects the testis to the spleen, whereas in the discontinuous form the splenic tissue is attached to the gonad and not continuous with the main body of the spleen (Ferron and Arce, 2013). Approximately 30% of affected individuals have cryptorchidism, with the majority of cases abdominal and bilateral (59%), and 65% and 26% involving the left and right sides, respectively (Cortes et al, 1996). The continuous form of splenogonadal fusion is more commonly syndromic, associated with limb defects, micrognathia, microglossia, anal atresia, and pulmonary hypoplasia (McPherson et al, 2003) and less commonly with cardiac defects, cleft palate, imperforate anus, and myelomeningocele (Lin et al, 2010). The discontinuous form can manifest as a testicular mass, with distinctive ultrasound findings that include a somewhat hyper-echoic mass (relative to testis) that contains multiple hypoechoic

nodules and obvious vascularity (Ferron and Arce, 2013). The pathogenesis of splenogonadal fusion is unknown but, based on the constellation of defects observed, is hypothesized to represent a developmental field defect with aberrant migration of spleen cells occurring at 5 to 8 weeks' gestation. Most cases are found incidentally at the time of orchidopexy or inguinal hernia repair or with scrotal swelling related to illness-related reactive changes within the splenic tissue. Testicular malignancy is reported rarely in association with cryptorchidism and not likely related to the splenic anomaly. Treatment should focus on recognition of the defect at the time of orchidopexy and avoidance of unnecessary orchiectomy.

Transverse testicular ectopia may occur as an isolated anomaly in otherwise normal males with cryptorchidism or vanishing testes, or in association with persistent müllerian duct syndrome in 20% to 50% of cases (De Luna et al, 2003; Wuerstle et al, 2007; Thambidorai and Khaleed, 2008). The classic presentation is inguinal hernia with contralateral nonpalpable testis, although both testes may be palpable in the same hemiscrotum. The cause may be related to mechanical hindrance to descent by fusion of wolffian duct derivatives (Chacko et al, 2006) or persistent müllerian ducts, or to a primary gubernacular defect. It is interesting to note that in transgenic *Ins13*^{-/-} mice, complete loss of the gubernacular attachment, transverse ectopia, and/or torsion was observed (Nef and Parada, 1999; Zimmermann et al, 1999). Laparoscopy is a useful adjunct in diagnosis and treatment. Orchidopexy may be performed using open surgical or laparoscopic techniques, but in cases of vasal fusion the involved testis is mobilized ipsilaterally and a trans-septal approach used to place the testis in the contralateral scrotum (Chacko et al, 2006; Thambidorai and Khaleed, 2008).

MANAGEMENT

Surgical correction of cryptorchidism is indicated to optimize testicular function, potentially reduce and/or facilitate diagnosis of testicular malignancy, provide cosmetic benefits, and prevent complications such as clinical hernia or torsion. Except in certain cases of associated complex medical illness or in the post-natal period, treatment should proceed after confirmation of the diagnosis. An algorithm has been established and published as part of the American Urological Association (AUA) cryptorchidism guideline (Kolon et al, 2014) (see Fig. 148-7), which outlines the recommended approach to palpable and nonpalpable testes in patients confirmed to have an undescended testis by an experienced examiner.

In infants, observation is indicated for the first 6 postnatal months to allow spontaneous testicular descent. If spontaneous testicular descent does not occur, surgical treatment after 6 months of (corrected gestational) age is indicated. Support for this approach is based on the following rationale: (1) Spontaneous descent is unlikely in full-term males after age 6 months (Wenzler et al, 2004), (2) testicular growth is restored after early orchidopexy (Kollin et al, 2007), and (3) orchidopexy for abdominal testes may be facilitated in young infants, soon after the hormonal surge. In boys with a history of prematurity, spontaneous descent may be delayed, and therefore observation is continued for 6 months beyond the expected date of delivery or, especially if testicular position is marginal, until a year of age. After spontaneous testicular descent, continued observation is needed because of the risk for recurrent cryptorchidism or testicular reascent.

Investigators in the Netherlands (Sijstermans et al, 2006; Eijsbouts et al, 2007) adopted an observational approach to boys with acquired cryptorchidism and reported spontaneous descent in 75 of 132 (57%) and 98 of 129 (76%) testes, respectively, most by midpuberty. The mean volume of descended testes in the study by Eijsbouts and colleagues was closer to those of normal contralateral testes as compared with boys who underwent orchidopexy. However, in both of these series, high scrotal testes comprised the majority of those that descended, and low scrotal "unstable" testes (likely retractile) were also included. On the other hand, Eijsbouts and colleagues reported that in 19 of 82 unilateral cases the patients had

Figure 148-11. Splenogonadal fusion. A case of continuous splenogonadal fusion in a boy with a left nonpalpable testis, with fusion to the spleen as identified by laparoscopy.

undergone previous contralateral orchidopexy and that 10 boys required orchidopexy because of clinical hernia, pain, or torsion, suggesting a higher likelihood of true cryptorchidism in these patients. In follow-up studies of 391 boys with 464 acquired cryptorchid testes, 90% of high scrotal and 64.5% of inguinal or nonpalpable testes descended spontaneously at a mean age of 12.9 years (Hack et al, 2010). In contrast, a study from the same institution showed that testicular volumes were significantly smaller for age in 155 postpubertal patients who had undergone orchidopexy at diagnosis (the majority before puberty) after a mean of 6.6 ± 3.8 years' follow-up (van der Plas et al, 2013c). Because these individuals were selected for orchidopexy and the majority (92%) had suprascrotal testes, they are likely not comparable to the group of boys treated after puberty at the same institution (Hack et al, 2010). Furthermore, these studies were not randomized and provided no long-term data regarding functional outcome. Consequently, they fail to provide strong evidence in support of observation as the recommended approach for cases of acquired cryptorchidism.

Medical Therapy

Hormonal therapy has been used for a variety of indications in patients with cryptorchidism, including differentiation of retractile from true undescended testes, stimulation of testicular descent or germ cell maturation, and as an adjunct to abdominal orchidopexy. **Hormone therapy is not currently recommended, given the lack of rigorous data supporting its efficacy** (Thorsson et al, 2007; Kolon et al, 2014).

Several published reports address the usefulness of hormonal therapy in distinguishing retractile from true undescended testes. In prospective series reporting the response of putative retractile testes to hCG, success rates vary from 58% to 100% and may be dependent not only on age, degree of retractility, and accuracy of diagnosis, but also on the dosage regimen used (Rajfer et al, 1986; Miller et al, 2003; Metin et al, 2005). These data suggest that hCG fails to reliably distinguish retractile from cryptorchid testes and therefore does not eliminate the need for serial examinations in these patients.

Luteinizing hormone–releasing hormone (LHRH) and/or hCG has been used as hormonal therapy to induce descent of testes for over 70 years based on the premise that androgens promote testicular descent, but efficacy is questionable (Pyorala et al, 1995; Henna et al, 2004; Thorsson et al, 2007). Although the efficacy of either hormonal treatment is about 20% and superior to placebo in randomized trials, this effect is not clearly clinically significant. Overall, the evidence from rigorous studies indicates that LHRH therapy is marginally more effective than placebo, and although not studied in randomized placebo-controlled trials owing to its route of administration, hCG also shows limited efficacy. Other uses of hCG, including treatment of acquired cryptorchidism and facilitation of palpability and/or treatment of the abdominal testis (Polascik et al, 1996; Baker et al, 2001; Bukowski et al, 2001), also have limited efficacy.

The question of the effect of therapeutic doses of hCG or LHRH on germ cell development has been addressed in several conflicting studies that are limited by small sample size, absent or suboptimal randomization, and variable availability of biopsy data (Ong et al, 2005). In small, retrospective studies, hCG treatment was associated with increased germ cell apoptosis at biopsy and lower adult testis volume (Dunkel et al, 1997), and previous hCG or LHRH therapy was associated with reduced germ cell counts in 1- to 3-year-old boys as compared with surgery alone (Cortes et al, 2000). In contrast, Schwentner and colleagues randomized young boys (mean age 33 months, 21 per group) to LHRH or no hormonal therapy before surgery and reported that mean germ cell count was higher (1.05 ± 0.71) in LHRH-treated than in nontreated (0.52 ± 0.39) testes (Schwentner et al, 2005). In view of a lack of large prospective studies, it is unclear if hormone therapy for cryptorchidism is beneficial or harmful to germ cells in the short or long term.

Hadziselimovic and colleagues have advocated use of low-dose, long-term (every other day for 6 months) LHRH analogue (buserelin) therapy for stimulation of germ cell development in conjunc-

tion with orchidopexy. In a retrospective study of nonrandomized, non-age-matched patients receiving buserelin versus surgery only, germ cell counts were significantly higher in the treated group (Hadziselimovic et al, 1987b). A subset of patients from this same cohort with the most severe testicular histology underwent rebiopsy after completion of therapy and were compared with a group of boys (8) of unknown age who required reoperative orchidopexy (Hadziselimovic et al, 1987a). A significant improvement in testicular histology was seen in the buserelin-treated but not the surgical group. Similarly, in a smaller select group of boys treated with low doses of a related LHRH agonist, nafarelin, improved histology was observed in one or both testes at rebiopsy in 8 of 12 boys. In a randomized study of clinically matched boys receiving buserelin plus hCG, placebo plus hCG, or surgery alone (19 to 25 per group), germ cell counts were also significantly higher in those treated with buserelin (Bica and Hadziselimovic, 1992). In a nonrandomized retrospective study, buserelin-treated males (most also received hCG) with a history of unilateral cryptorchidism and poor pretreatment germ cell counts had much higher sperm counts than patients who underwent surgery only (15 patients per group) (Hadziselimovic, 2008). Unfortunately, these two groups were small and not clinically matched prospectively to limit other potential confounding factors such as testicular position, and sperm counts in the surgery-only group were lower than typical for unilateral cryptorchidism. Overall, these studies provide preliminary, suggestive evidence that buserelin may have both short- and long-term effects on testicular histology and/or fertility potential. However, the suboptimal design of the studies on which this evidence is based mandates that future well-designed prospective studies be conducted before buserelin treatment can be used routinely in cryptorchidism. In summary, little if any high-quality evidence exists showing benefit of hormonal therapy for cryptorchidism or for stimulation of germ cells.

Surgical Approach to the Palpable Testis

Timing of Surgery

The recommendation that surgical intervention proceed once failure of spontaneous descent is confirmed is now standard (Chan et al, 2014; Kolon et al, 2014) but is not new. Despite this, the average age at which orchidopexy is performed remains approximately 4 years in many series (Barthold and Gonzalez, 2003; Kokorowski et al, 2010; Bayne et al, 2011; Snodgrass et al, 2011; Barthold et al, 2012; Bradshaw et al, 2014; Nah et al, 2014). A review of the Pediatric Health Information System (PHIS) database by Kokorowski and colleagues demonstrated that only 18% of 28,204 boys who underwent surgery did so by 1 year of age. The reason for delayed intervention likely reflects a combination of factors, primarily including delayed referral of congenital cases and the occurrence of acquired cryptorchidism. Cases of congenital cryptorchidism may go undetected or untreated in infancy owing to prematurity or other morbidity, may undergo longer than necessary observation for spontaneous descent, or may represent cases of undetected reascent after spontaneous descent in infancy. Delay may also be exacerbated by difficulty in distinguishing undescended from retractile testes.

The traditional approach to surgical treatment of palpable testes is inguinal orchidopexy with repair of an associated hernia if present (Hutcheson et al, 2000a), although a primary scrotal approach as originally described and advocated by Bianchi and colleagues (Bianchi and Squire, 1989; Iyer et al, 1995) is an alternative approach. An option for pubertal and postpubertal boys is orchiectomy, especially if the testis is abdominal or difficult to mobilize because poor spermatogenesis and hypotrophy are usually present and the risk of CIS and torsion exist (Rogers et al, 1998).

Inguinal Orchidopexy

After induction of anesthesia, the patient is re-examined to confirm that the testis is palpable and to identify the lowest testicular

Figure 148-12. Inguinal orchiopexy. A, An incision is made at or below the inguinal crease superolateral to the pubic tubercle. B, The external oblique fascia is incised to expose the canal. C, The gubernaculum is transected distal to the sac. D, The internal spermatic fascia is incised. E, The tunica vaginalis is opened over the testis, and F, the incision is extended proximally along the length of the cord. G, The sac is mobilized to the level of the internal inguinal ring and suture-ligated. H, A transverse scrotal incision is made and a subdartos pouch created. I, A large clamp or a finger can be used to create a tunnel just anterior to the pubis. J, The testis is passed into the scrotum. K, Existing appendages are excised. L, The testis is secured within the pouch. M, Closure is completed with absorbable sutures.

position. In the standard inguinal approach (Fig. 148-12), a low transverse incision in Langer lines at or below the inguinal crease is made superolateral to the pubic tubercle. Dissection of the subcutaneous tissue should include a search for a testis within the SIP. After identification of the external ring, the external oblique fascia is incised to expose the canal, with care taken to avoid injury to the ilioinguinal nerve. Testis position is recorded relative to the inguinal canal. The spermatic cord is isolated and the remnant is dissected distally to its attachment to the gubernacular remnant. Dissection of the gubernaculum distal to the sac will avoid potential injury to a long-looping vas. Longitudinal incision of the internal spermatic fascia allows free mobilization of an intact hernia sac, if present, and minimizes skeletonization of the vas and spermatic vessels. Alternatively, the sac may be opened overlying the testis and the incision extended proximally along the length of the cord. Once isolated, the sac is mobilized to the level of the internal inguinal ring and suture-ligated. Incision of the internal spermatic and transversalis fascia at the level of the ring facilitates additional retroperitoneal mobilization of the vas and vessels, if needed. Further maneuvers to provide spermatic cord length include transection of lateral fascial bands along the cord, cranial retroperitoneal dissection, medial transposition of the testis beneath the epigastric vessels (Prentiss maneuver), and, if required, cranial extension of the incision. Very rarely, the testis cannot be brought to dependent scrotal position after these maneuvers and a two-stage procedure may be considered as an alternative to orchiectomy, which is preferentially reserved for visibly abnormal or atrophic testes, postpubertal patients, or cases associated with insufficient vasal length.

After mobilization of the spermatic cord, a transverse scrotal incision is made and a subdartos pouch created. A large clamp or

a finger can be used to create a tunnel just anterior to the pubis. The testis is passed through an opening in the dartos without twisting of the spermatic cord. Existing appendages should be excised and the epididymis inspected and any anomalies recorded. Recording of testicular volume by direct caliper measurement in three dimensions and similar (estimated) measurements of contralateral testicular volume can establish a baseline for postoperative assessment. Secure fixation of the testis within the pouch can be achieved by tension-free closure of the opening in the dartos around the cord, incorporating the cut edge of the tunica vaginalis. If needed, additional absorbable fixation sutures can be placed between the visceral tunica vaginalis and the dartos. Alternatively, suture fixation through the tunica albuginea to the scrotal wall may be performed. There is a theoretic risk of injury to the testis via inflammatory or vascular insult with suture placement through the tunica albuginea. Closure is completed with absorbable sutures. Supplemental local or regional techniques for perioperative pain control are advisable and may include local anesthetic infiltration, ilioinguinal nerve block, or caudal anesthesia; the latter is particularly useful in younger patients undergoing bilateral inguinal or concomitant penile surgery.

Testicular biopsy has been performed routinely in some centers and has been advocated by Hadziselimovic and colleagues as a method to determine prognosis for fertility (Hadziselimovic and Zivkovic, 2007). This approach is controversial and not recommended outside of research protocols because it does not change the current approach to treatment (Ritzen et al, 2007; Beckers and van der Horst, 2008). The risk to the cryptorchid testis from biopsy is theoretic; although long-term effects do not appear to include increased risk of microlithiasis or antisperm antibody formation

(Patel et al, 2005), other more subtle effects cannot be excluded from the available data. Biopsy is indicated in cases of sexual ambiguity or if clinical evidence of testicular dysgenesis is present.

Complications of inguinal orchidopexy are uncommon; those of greatest significance include testicular retraction and atrophy. Docimo reported a comprehensive review of the orchidopexy literature in 1995, before the routine use of laparoscopic orchidopexy, and including both palpable and nonpalpable testes (Docimo, 1995). He concluded that the overall risk of atrophy or nonscrotal position was approximately 15% overall in published reports, significantly higher in abdominal or peeping testes (24%) compared with those distal to the internal ring (10%) and higher in boys undergoing surgery after 6 years of age. More recently, analysis of boys with postoperative testis retraction over an 18-year period at a single institution consisted of less than 2% of 1886 primary open orchidopexies performed during that period, with a slightly higher risk of failure in older boys (McIntosh et al, 2013). However, these boys were not actively followed by the authors, so detailed clinical data were not available and the frequency of testicular atrophy could not be defined. In another series of 418 orchidopexies in 356 boys from a single institution with a median of 1-year follow-up, the risk of atrophy was 1.9% and of nonscrotal position was 10.3% (Thorup et al, 2011a). However, in this series the risk of complications was higher when surgery was performed at a younger age, and all boys with acquired cryptorchidism had a successful result. The authors concluded that earlier orchidopexy may be more technically demanding and supported the concept that expertise of the surgeon is relevant for more challenging cases.

A minimum of 6 months' follow-up is recommended to determine postoperative testis position and size. Long-term follow-up should be considered for counseling of the patient regarding fertility issues, risk of testicular malignancy, and self-examination. Torsion of a scrotal testis after orchidopexy has been reported but is very rare, and the risk may be minimized by routine extravaginal testicular fixation in a subdartos pouch. If complete intrascrotal testicular atrophy occurs postoperatively, further intervention is not needed, but the option of testicular prosthesis placement should be offered to the patient and family (Bodiwala et al, 2007). Implantation of a testicular prosthesis should occur at least 6 months after any scrotal procedure or after puberty and is best performed through an inguinal approach. Fixation of the prosthesis to the dartos and closure of the scrotal fascia above the implant using purse-string nonabsorbable suture are required. Complications including displacement, pain, or infection occur in less than 5% of cases. Clinical experience suggests that cryptorchid boys may request prosthesis implantation less frequently than males with acute testicular loss after puberty (Bodiwala et al, 2007).

Reoperation is indicated if a testis is nonscrotal after orchidopexy. If the testis is prescrotal, a primary scrotal approach can be considered and may allow adequate mobilization of the testis. If inguinal exploration is needed to provide sufficient cord length, several approaches are available. Redman described a primary or secondary orchidopexy that involves a lateral approach to the cord after mobilization of the external oblique and cremaster fasciae (Redman, 2000). This approach avoids traversal of the previously scarred layers anterior to the cord and affords a clearer view of the anatomy. Cartwright and colleagues described mobilization of the intracanalicular cord with an overlying patch of external spermatic fascia (Cartwright et al, 1993). The importance of correcting a persistently patent processus vaginalis and/or of adequate retroperitoneal mobilization of the cord in cases of high recurrent cryptorchidism has been stressed (Redman, 2000; Pesce et al, 2001; Ziylan et al, 2004). The results of secondary orchidopexy appear to be similar to the primary procedure, although the risk of vascular and vasal injury is theoretically higher (Pesce et al, 2001).

Trans-Scrotal Orchidopexy

A primary scrotal approach can be considered when the testis is palpable (Bianchi and Squire, 1989; Iyer et al, 1995; Cloutier et al, 2011) although some surgeons reserve this approach for testes that

Figure 148-13. Trans-scrotal orchidopexy. Various scrotal incisions that have been reported; A, Bianchi incision (Bianchi); B, transverse low scrotal approach (Misra); C, midline scrotal approach. (From Cloutier J, Moore K, Nadeau G, et al. Modified scrotal [Bianchi] mid raphe single incision orchiopexy for low palpable undescended testis: early outcomes. J Urol 2011;185:1088–92.)

are close to or can be drawn into the scrotum (Russinko et al, 2003; Rajimwale et al, 2004; Bassel et al, 2007; Takahashi et al, 2009). After induction of anesthesia, the patient is re-examined to confirm the position of the testis. An incision along the superior scrotal border is made as described by Bianchi and Squire for any palpable testicles. Alternatively, a transverse low scrotal approach (Misra et al, 1997) and midline scrotal approach (Cloutier et al, 2011) have been described for those testes that can be drawn into the scrotum (Fig. 148-13). After the testis has been delivered, the distal sac and overlying cremaster are mobilized proximally as far cranially as possible, "high above the inguinal canal" (Iyer et al, 1995). Some cases require conversion to an inguinal approach for ligation of the sac or to gain further length on the spermatic cord (Parsons et al, 2003; Dayanc et al, 2007). Rajimwale and colleagues confirmed in several cases that the hernia sac had been effectively ligated above the internal ring via the scrotal incision when a secondary inguinal incision was required for further mobilization of the testis (Rajimwale et al, 2004). Fixation sutures through the tunica albuginea have been used in many series of scrotal orchidopexy (Jawad, 1997; Russinko et al, 2003; Bassel et al, 2007; Dayanc et al, 2007; Takahashi et al, 2009), followed by placement of the testis in a subdartos pouch. In an extensive review of the literature by Gordon and colleagues, additional inguinal incisions were needed in 4.4% and there were early postoperative complications in 1.6% of cases (Gordon et al, 2010). The single institution long-term results reported by these authors included a reoperative rate of 4.9% and a 0.6% incidence of testicular atrophy. In a literature review of 1558 cases in 20 series reporting 3 months to 5 years of follow-up, a hernia was present in 30% and 3.5% of cases required an inguinal incision (Novaes et al, 2013). Complications included recurrence (0.6%), testicular atrophy or hypotrophy (0.3%), hematoma (1.4%), wound infection (0.8%), and vasal injury (1 case), with a low overall complication rate of 3%. Scrotal incision orchidopexy is used selectively in many series, but the available evidence suggests that efficacy and complication rates are similar to those of standard inguinal orchidopexy.

Surgical Approach to the Abdominal Testis

Once an abdominal testis has been identified, the surgeon must decide whether to proceed with an open or laparoscopic, one- or two-stage orchidopexy with possible spermatic vessel transection. Orchiectomy is appropriate for patients with testes that are poorly viable and/or at higher risk for tumor, which may include testes in postpubertal patients or very small or dysgenetic testes in postpubertal patients, and is in our opinion best performed laparoscopically.

Open Transabdominal Orchidopexy

Extensive dissection of the vas and vessels is facilitated by a longitudinal opening of the internal oblique and peritoneum through an extended inguinal incision (Kirsch et al, 1998) or via a higher incision medial to the pubic tubercle and a preperitoneal approach (Jones and Bagley, 1979; Gheiler et al, 1997). In the procedure described by Jones and Bagley, the internal ring is approached via a muscle-splitting incision, the peritoneum is opened, the testis delivered, and the vas and vessels freed from their peritoneal attachments. A tunnel is created to the scrotum and the testis is secured in place as for an inguinal orchidopexy. The reported success rate for this procedure for abdominal testes was 95% (Gheiler et al, 1997).

Laparoscopic Orchidopexy and Fowler-Stephens Orchidopexy

Operative laparoscopy emerged over 15 years ago as the procedure of choice for abdominal orchidopexy (Caldamone and Amaral, 1994; Jordan and Winslow, 1994), and the basic surgical approach and high success rates have stood the test of time (Table 148-1). The feasibility of primary versus Fowler-Stephens orchidopexy depends on the length of the vas and vessels, presence or absence of looping ductal structures, and age of the patient. Although laparoscopy allows the surgeon to assess some of these features before choosing a specific surgical procedure, the choice may be difficult (Yucel et al, 2007). Observed testicular position alone may correlate poorly with the ultimate length of the cord after mobilization.

After induction of anesthesia, a further attempt to palpate the testis is made, although a laparoscopic approach may be considered for mobilization of high canalicular testes as well. After decompression of the bladder and stomach, an infraumbilical 5-mm trocar is placed for passage of a 30-degree lens, and both internal rings are visualized. An open Hasson or Bailez technique is preferable for umbilical trocar placement in the pediatric age group to minimize risk of injury (Franc-Guimond et al, 2003). CO₂ pneumoperitoneum to a maximum pressure of 8 to 12 mm Hg is used. The size and position of the testis within the abdomen are determined before further decision making. For single-stage laparoscopic orchidopexy, additional 2- or 3-mm trocars are placed in the right and left lower quadrants to triangulate with the umbilicus and ipsilateral internal ring, or in the midclavicular line at the level of the umbilicus bilaterally for bilateral abdominal testes. The major steps are mobilization of any structures extending distal to the internal ring, including epididymis and vas and gubernacular remnant, transection of the peritoneum lateral to the vessels and distal to the vas, and proximal mobilization of the vessels while maintaining collateral blood supply between the vas and spermatic vessels. Samadi and colleagues advocate initial mobilization of the gubernaculum to be used as a handle for further mobilization of the testis, and minimal use of cautery during this maneuver (Samadi et al, 2003). Ability to mobilize the testis to the opposite internal ring has been used as a measure of adequate length for placement in the scrotum but was not predictable in some series. Once mobilized, the testis is brought through a new hiatus medial to the epigastrics and lateral to the medial umbilical ligament or through the existing internal inguinal ring. This maneuver can be completed using a trans-scrotal clamp or an additional port passed up from the scrotum. With tension on the extra-abdominal testis, peritoneal attachments overlying the cord can be more easily transected, thus providing addi-

tional length. In some cases the testis can only be brought into the upper scrotum; the long-term adequacy of this approach is not clear. Excessive tension on the vessels during placement of the testis should be avoided, because injury or avulsion of the spermatic vessels may occur (Esposito et al, 2002). A key strategy should be preservation of the blood supply between the vas and spermatic artery during dissection so that the Fowler-Stephens procedure can be performed if necessary.

Formal closure of the dissected internal ring is not necessary (Handa et al, 2005; Riquelme et al, 2007); indeed, previous experience with open hernia repair suggests that ligation is not needed if the internal ring is dissected (Mohta et al, 2003). No inguinal hernias were identified a mean of 41 to 50 months after laparoscopic orchidopexy in a retrospective series in which formal closure of the internal ring was performed in 54% of cases (Khairi et al, 2013). A contralateral patent processus vaginalis was identified in 9% of boys undergoing laparoscopic orchidopexy in one series, and laparoscopic repair was performed and recommended (Palmer and Rastinehad, 2008). However, the necessity for this approach in preventing clinical hernia formation is questionable based on studies of boys undergoing laparoscopic or open hernia repair (Schier, 2007).

For testes that are not near (variably defined as 2 to 4 cm above) the internal inguinal ring, transection of the spermatic vessels as originally described by Fowler and Stephens may be necessary (Fowler and Stephens, 1959); a long-looping vas facilitates but is not required for testicular mobilization to the scrotum. The Fowler-Stephens procedure is now typically performed laparoscopically with spermatic vessel clipping (Bloom, 1991) followed by laparoscopic or open testicular mobilization in the same setting, or in a staged approach 6 months later. The peritoneum should be left intact over the vasal vessels, and the gubernacular vessels should be left intact if possible. Although most surgeons transect the spermatic vessels at least 1.5 to 3 cm above the testis, Koff and Sethi proposed that ligation close to the testis is preferable (Koff and Sethi, 1996). This group subsequently studied the effect of low versus high transection of the vessels in prepubertal rats and showed a reduction in adult testicular sperm numbers that was similar in both groups (Srinivas et al, 2005). In human studies, testicular biopsies before and after spermatic vessel transection also showed a reduction in germ cell count, a finding that was significant in younger boys (Thorup et al, 1999; Rosito et al, 2004). In general, the preferred approach is avoidance of spermatic vessel transection whenever possible; the available data suggest this is possible in the majority of cases of abdominal orchidopexy. In rare cases, particularly if the testis is retrovesical, the vas is too short to allow scrotal placement of the testis, and orchiectomy is ultimately required (Perovic and Janic, 1997).

The success rates for laparoscopic procedures as shown in Table 148-1 appear to compare favorably with the corresponding 74%, 63%, and 77% overall success rates for open surgical and one-stage and two-stage Fowler-Stephens procedures, respectively (Docimo, 1995). The available data suggest that a primary procedure is more consistently successful (>90% in most series) than a Fowler-Stephens approach (variable success of 60% to 97%). In directly comparing the results of 156 abdominal orchidopexies at a single institution, Stec and colleagues observed significantly better results for a primary open (89% success) or laparoscopic (97%) approach than for one-stage (63%) or two-stage (68%) Fowler-Stephens procedures (Stec et al, 2009). Recent meta-analyses and/or systematic reviews of surgical treatment of abdominal testes (Elyas et al, 2010; Guo et al, 2011; Penson et al, 2013; Kolon et al, 2014) are primarily low-quality retrospective series with few, if any, adequately powered prospective controlled studies. Pooled success rates for primary one-stage Fowler-Stephens and two-stage Fowler-Stephens procedures are approximately 95%, 80%, and 85%, respectively. The available evidence suggests no clear difference in efficacy between open and laparoscopic procedures. Variation in reported results among series may reflect inherent selection bias resulting from differences in patient age, testicular position or quality, length of follow-up, and/or criteria used to define success, such as "intrascrotal" versus

TABLE 148-1 Results of Laparoscopic Orchidopexy*

PROCEDURE	SERIES	PATIENTS/ TESTES	AGE	FOLLOW-UP	HIGH POSITION	TOTAL ATROPHY	OVERALL SUCCESS

*Reported results of abdominal, one-stage, and two-stage Fowler-Stephens (FS) orchidopexy in series with 30 or more treated testes (≥25 for one-stage FS). Age is expressed as the mean for the entire series unless otherwise noted. *High position* refers to testes not in dependent scrotal position.

†Position within scrotum not clearly documented.

‡Em dashes (—) indicate that information was insufficient.

§Series in which partial atrophy was also noted. *Overall success* refers to the frequency of nonatrophic testes in satisfactory scrotal position according to variably detailed criteria used by the authors.

"dependent scrotal" position. Despite their limitations, the available data seem to suggest that primary orchidopexy without transection of the spermatic vessels is preferable whenever possible. Some authors recommend that ultrasound be used to confirm testicular viability postoperatively (Esposito et al, 2002). Other complications of laparoscopic orchidopexy are rare and potentially include bladder or vascular injury, hypercapnia, and delayed small bowel obstruction (Esposito et al, 2003; Hsieh et al, 2009).

Laparoscopic techniques may be applicable in unusual cases, including bilateral orchidopexy, abdominal wall defects, polyorchidism, splenogonadal fusion, and transverse testicular ectopia with or without persistent müllerian ducts. Many authors recommend simultaneous bilateral abdominal orchidopexy (Kaye and Palmer, 2008), but the surgeon should consider a staged approach if both testes are very high or the viability of a testis is questioned during the course of orchidopexy as noted in Kaye and Palmer's algorithm. Depending on the outcome of the first procedure at 6 months' follow-up, the surgeon can choose an operative approach to the contralateral side that would appear to minimize the risk of bilateral testicular atrophy (Thorup et al, 2007). Some surgeons have considered microvascular orchidopexy to be a preferred approach to the solitary abdominal testis, particularly with historical success rates of 88% as compared with lower rates for open procedures (Docimo, 1995). At a center with substantial experience using the microvascular approach, long-term success rates of 96% for standard and 88% for laparoscopically assisted autotransplantation were reported (Bukowski et al, 1995; Tackett et al, 2002). The advantage of this approach is preservation of the spermatic vessels, at the cost of longer operative time and requirements for an experienced microvascular surgeon and hospital stay.

PROGNOSIS

Despite the common occurrence of cryptorchidism and voluminous literature on the subject, many gaps exist in our present understanding of the factors contributing to long-term outcome. This is likely because of the expectation that surgical correction will be successful in most cases, and prospective studies into adulthood are difficult and not routine in otherwise healthy males. These studies would need to (1) account for multiple confounding variables, many of which are incompletely defined, including severity of the disease (e.g., based on testicular position, laterality, epididymal anomalies), multifactorial cause, age at surgery, exposure to hormone therapy, and type of procedure performed, and (2) use standardized methodology based on adequate follow-up and complete documentation of complications to report results. Well-designed studies that provide higher-quality evidence are clearly needed.

Risk of Subfertility

Although there is strong evidence that a history of cryptorchidism is associated with subfertility in individual patients, the effects of age at diagnosis, type of treatment, and/or severity of disease on outcome remain incompletely defined. Major limitations in the interpretation of cryptorchidism outcome studies include selection bias resulting from incomplete follow-up of large patient cohorts and heterogeneity of diagnosis and timing/type of treatment. In a large review of retrospective studies published in the 50 previous years that did not take these concerns into consideration and did not include a statistical meta-analysis, Chilvers and colleagues reported overall rates of oligospermia and/or azoospermia of 75% for formerly bilaterally and 43% for formerly unilaterally cryptorchid men (Chilvers et al, 1986). The limited available data comparing earlier (age younger than 9) and later treatment did not show differences in the frequency of subfertility after unilateral (281 cases) or bilateral (123 cases) orchidopexy. Similarly, subset analysis failed to identify any effect of hCG treatment. Two subsequent large studies of semen parameters in men who underwent orchidopexy in childhood also found differences between bilateral and unilateral cryptorchidism but less consistent overall results. Okuyama and associates (Okuyama et al, 1989) reported normal

sperm density in 0%, 72%, 77%, and 42% of men after bilateral orchidopexy (61), unilateral orchidopexy (149), unilateral orchiectomy (26), and no treatment (38) for inguinal testes without hormone therapy. All of these patients underwent three semen analyses. In contrast, Gracia and colleagues reported normal semen samples in 10 of 55 (18%) men with a history of bilateral and 57 of 171 (33%) with previous unilateral cryptorchidism (Gracia et al, 2000). The majority of testes in this series were canalicular, and 80% of subjects received preoperative hCG therapy. These authors noted no differences based on testicular position, and semen quality was not correlated with age of surgery in either series. In 91 patients with unilateral cryptorchidism who underwent orchidopexy after the onset of puberty (age 14 to 29), the risk of azoospermia or oligospermia was 84% (Grasso et al, 1991) a trend in keeping with the data reported previously (Okuyama et al, 1989). In contrast, Puri and O'Donnell studied 142 men who underwent unilateral (119) or bilateral (23) orchidopexy at 7 years of age or older; these researchers reported normal sperm density in 84% and 50% of patients, respectively (Puri and O'Donnell, 1988).

Changes in the pattern of care over time, particularly earlier surgery without the confounding effects of hormonal therapy, may alter prognosis. However, potential benefits of early orchidopexy have not been shown because the mean age of operation for patients included even in more recent studies remains high, at over 7 years (Vinardi et al, 2001; Trsinar and Muravec, 2009; Kraft et al, 2012; van Brakel et al, 2013, 2014), and the number of participants in each series was fewer than 100. In these studies, the prevalence of normal sperm counts is similar to that reported previously, ranging from 60% to 84% and 18% to 53% in prior unilateral and bilateral cryptorchidism, respectively. Semen analysis data appear to be superior in a small series of 51 men who underwent orchidopexy before age 2, with normal sperm count in 96% of unilateral (27) and 75% of bilateral (24) cases (Feyles et al, 2014). The highest testis was abdominal in 6 (12%) and intracanalicular in 20 (39%) cases, and 29 boys (57%) received preoperative hormonal therapy. Although interesting, the reason for inconsistency with prior studies of bilateral cryptorchidism will require further studies.

Several studies suggest that mean germ cell counts obtained at biopsy correlate with long-term fertility potential as measured by mean semen analysis parameters (Engeler et al, 2000; Cortes et al, 2003a; Rusnack et al, 2003), although the usefulness of total germ cell counts as a predictor of fertility in individuals is limited, particularly in individual cases. More recent reports investigated the use of Ad spermatogonia number as a better predictor of semen quality in adulthood. Hadziselimovic and colleagues reported a strong correlation between the number of Ad spermatogonia in cryptorchid testes and sperm count in adulthood after previous unilateral or bilateral orchidopexy with or without prior hormonal therapy (Hadziselimovic et al, 2007; Hadziselimovic and Hoecht, 2008). In non-hormonally treated patients, total sperm count was normal (>40 million per ejaculate) in 84% of 25 men who had Ad spermatogonia present in biopsy specimens from both testes, whereas it was subnormal in all 18 men (10 of the 19 men in this series with a history of bilateral cryptorchidism) in whom biopsy results were negative for Ad spermatogonia. Total germ cell counts were reportedly not predictive of sperm concentration in this series (Hadziselimovic and Hoecht, 2008). In a larger series of men with prior unilateral (91) or bilateral (19) cryptorchidism, Kraft and colleagues observed lower mean sperm counts and higher FSH levels in adulthood when bilateral biopsy at surgery showed severe loss of germ cells or abnormal Ad spermatogonia counts, but, likely because of the variability of the data, group means remained within normal range and/or were not statistically significant, confirming that even analysis of Ad spermatogonia does not always predict fertility potential in individuals (Kraft et al, 2012). The reported hormone levels in adulthood also do not predict fertility status. In view of the heterogeneity of the disease and its treatment, most studies are likely underpowered to detect clear associations between histologic and phenotypic variables and fertility potential as estimated by semen analysis. Nevertheless, both Ad spermatogonia count and germ cell absence are potentially useful measures of fertility prognosis, but may be more useful in cases of bilateral

cryptorchidism. Additional, larger prospective studies of these parameters in boys who underwent surgery in infancy are needed.

The use of semen analysis alone to define outcome and predict fertility potential has limitations. For example, a large population study of fertile and infertile men with fertile partners suggests that there is extensive overlap between semen parameters in men with and without proven paternity (Guzick et al, 2001). In this study, the authors established lower infertile threshold levels for density ($13.5 \times 10^6/\text{mL}$), motility ($>35\%$), and normal morphology ($>9\%$) than had been established by World Health Association criteria. About 3% of fertile men in this series had a sperm density below $10 \times 10^6/\text{mL}$, and measurements between 13.4 and $48 \times 10^6/\text{mL}$ were considered indeterminate. Repeated semen analyses, rarely performed in studies of formerly cryptorchid men, were reportedly necessary to provide reliable data in normal men (Oshio et al, 2004). However, the reliability of semen analysis in adolescents is not fully known. Christman and associates recently addressed this question in Tanner stage V youths (age younger than 25) being evaluated for cryptorchidism (48) or varicocele (31) (Christman et al, 2013). In this study, semen parameters were not highly reproducible between samples in the same individual, yet the computed intraclass correlation coefficient was considered substantially reliable, particularly for total sperm counts, suggesting that a single sample, especially when normal, may suffice in estimating fertility potential. When semen analysis results are abnormal, repeat samples should be obtained whenever possible.

Determination of paternity status is an alternative measure of fertility that should be considered when determining prognosis. Limitations of this approach include paternal discrepancy and variability in the timing and degree of interest in attempts at paternity. Although of concern and not ethically retrievable, a recent review (Bellis et al, 2005) found that the median level of paternal discrepancy in 17 studies of unselected populations in Europe and the Americas was only 3.7% (interquartile range, 2% to 9.6%). Two retrospective cohort studies of men with previous cryptorchidism assessed paternity in 145 (Gilhooly et al, 1984) and 40 (Cendron et al, 1989) cases. Together, these studies identified successful paternity in 100 of 123 (81%) men with a history of unilateral and 19 of 54 (35%) men with a history of bilateral cryptorchidism. Lee and colleagues published a series of well-designed case-control studies of fertility in cryptorchidism (Lee et al, 1996, 1997; Coughlin et al, 1999; Lee et al, 2000; Lee and Coughlin, 2001, 2002b; Lee, 2005). Questionnaire, hormone, semen analysis, and paternity data were analyzed for a large cohort of men who underwent orchidopexy between 1955 and 1975 and a control group of similar age who were matched for timing of unrelated surgery. For all married or cohabitating men, 32 of 88 (36%) former bilateral, 322 of 609 (53%) former unilateral, and 413 of 708 (58%) controls had fathered children. **Of those attempting paternity, 32 of 49 (65%) former bilateral, 322 of 359 (90%) former unilateral, and 413 of 443 (93%) controls were successful.** There were no significant differences between the unilateral and control groups and no differences among groups in the frequency of attempted paternity or in other lifestyle factors that could adversely affect fertility. The frequency of successful paternity did not differ among men with previous unilateral cryptorchidism who had undergone orchiectomy and the control group. Risk for infertility was increased after hCG treatment (RR 4.7, $P = .002$) but not with higher testicular position or age at orchidopexy. Sperm density was $13 \times 10^6/\text{mL}$ or lower in all 8 patients with bilateral cryptorchidism who were studied; however, 3 of these men had fathered children (Lee and Coughlin, 2001). Sperm density and motility were normal in 83% of men in the unilateral group, and morphology did not differ from control values. Although hormone levels alone did not correlate directly with fertility, abnormal levels of serum inhibin B or FSH and/or sperm density provided cumulative risk of decreased fertility. However, the authors concluded that prediction of infertility is difficult in the absence of azoospermia or severe oligospermia. These investigators also found differences in basal and stimulated LH and in serum testosterone when comparing fertile and infertile or subfertile formerly cryptorchid men, and suggested that global

testicular dysfunction occurs in cryptorchid males. Moreover, there is some evidence from these studies of a relationship among improved testosterone, inhibin B, and FSH levels in males who underwent earlier orchidopexy (Coughlin et al, 1999; Lee and Coughlin, 2002a).

In limited series, investigators have addressed the possibility of defective spermatogenesis in adult patients with persistently retractile testes or with milder forms of acquired cryptorchidism, with or without apparent spontaneous descent of the testis at puberty. In small, retrospective outcome studies, Puri reported 74% paternity and normal testicular volume in a series of 43 adults with untreated retractile testes in childhood (Puri and Nixon, 1977). Conversely, Nistal and Paniagua and Caroppo and colleagues identified 23 and 34 males, respectively, from infertility clinic data and identified poor semen parameters in the majority of patients, but the duration and severity of retractility were poorly documented (Nistal and Paniagua, 1984; Caroppo et al, 2005). Two series reported varying degrees of abnormal germ or Sertoli cell development in retractile testes of boys who underwent elective orchidopexy as compared with boys with descended testes; differences were qualitatively similar to findings in cryptorchid testes (Hadziselimovic et al, 1987a; Caucci et al, 1997). Han and colleagues compared 61 retractile with 83 cryptorchid testis biopsy specimens and noted similar trends but did not include a control group (Han et al, 1999). Methodologic limitations prevent clear differentiation of retractile from acquired undescended testes in these studies. Prospective studies of well-characterized patients are needed, but there is insufficient evidence to support an increased risk of infertility in uncomplicated cases of retractile testis.

Similarly, the outcome data for acquired cryptorchidism are difficult to interpret, because to date they are based on retrospective, nonrandomized studies that analyzed cases of both spontaneous descent at puberty and prior orchidopexy. In a retrospective series of 45 men with spontaneous descent of bilaterally undescended testes after age 10 by history (without clear documentation of congenital vs. acquired classification), testicular volumes were below 15 mL in 62% and sperm counts below 20 million/mL in 44% of patients (Bremholm Rasmussen et al, 1988). Investigators from the Netherlands who have followed boys with either congenital or acquired cryptorchidism recently reported follow-up fertility data (van Brakel et al, 2013, 2014). In prior publications from these institutions, the majority of the acquired group, particularly those with spontaneous descent at puberty, included high scrotal and low scrotal "unstable" testes (likely retractile) (Sijstermans et al, 2006; Eijsbouts et al, 2007; Hack et al, 2010). Van Brakel and colleagues observed no differences in semen parameters or hormone levels in small subgroups of men with a history of acquired cryptorchidism after spontaneous testicular descent (24) or orchidopexy (26) at puberty. The fertility potential of men with acquired (65) and congenital (62) cryptorchidism was similar and reflected prior studies showing a worse prognosis in bilateral cases. Few of the men studied had attempted paternity. Unfortunately, these investigators and others (Trsinar and Muravec, 2009) have reported difficulty in recruiting subjects, with only 12% to 31% of eligible individuals participating. Consequently, the ability to draw conclusions from the majority of studies, particularly in subgroup analyses, is compromised by insufficient sample size and potential bias. However, **available data provide strong evidence that fertility potential is compromised in men with a history of bilateral cryptorchidism, but the frequency of abnormal semen parameters in unilateral cases is higher than the relative risk of infertility as measured by paternity data.** Unfortunately, the number of formerly bilaterally cryptorchid men who have been comprehensively studied is limited. Although data suggest the possibility of an association between age at surgery and risk of infertility, further studies are needed to elucidate the relationships between these factors.

Risk of Testicular Germ Cell Tumor

The increased risk of TGCT in males with a history of cryptorchidism has been known for many years. Both seminoma and

nonseminomatous germ cell tumors (NSGCTs) develop from CIS of the testis, also called *intratubular germ cell neoplasia, unclassified* (ITGCNU), and are believed to be developmental in origin (Rajpert-de Meyts and Høie-Hansen, 2007). The hypothesis that persistent gonocytes are the precursors of ITGCNU has existed for some time, and recent gene expression data indeed support a common origin for the two cell types (Sonne et al, 2009). The histologic data suggesting that gonocytes fail to transform normally in cryptorchid testes may coincide with eventual transformation of these persistent cells into ITGCNU and TGCT. Using placenta-like alkaline phosphatase (PLAP) as a marker of ITGCNU, Engeler and colleagues identified PLAP-positive cells in 5% of 440 patients, most (82%) younger than 3 years, who had undergone testicular biopsy and orchidopexy many years previously (Engeler et al, 2000). Although up to 50% of adults with ITGCNU are expected to develop TGCT over time, no tumor was detected in the 15 of 22 affected individuals that the authors were able to evaluate a median of 21 years later. It is now recognized that several markers of undifferentiated spermatogonia, including PLAP, OCT3/4, c-KIT, NANOG, and SCF (stem cell factor, or kit ligand), show decreasing expression in the fetus and normally disappear after birth, but are re-expressed in ITGCNU and TGCT (Honecker et al, 2004; Cools et al, 2005; Høie-Hansen et al, 2005; Stoop et al, 2008) and may be upregulated postnatally in individuals with dysgenetic gonads at higher risk of malignancy (Rajpert-De Meyts et al, 2004). The observation that PLAP-, c-KIT-, or OCT3/4-positive germ cells persist beyond the first few months of life in cryptorchid testes is consistent with known delayed maturation of germ cells (Thorup et al, 2013; Kvist et al, 2014). PLAP may have a role in defining the prognosis for spermatogenesis in cryptorchidism (Thorup et al, 2013), but to date no germ cell marker can differentiate between delayed germ cell maturation and ITGCNU in this population. In an isolated finding, Cortes and colleagues identified multinucleated spermatogonia in 13 (8%) of 163 consecutive patients undergoing biopsy at the time of orchidopexy (Cortes et al, 2003b). This occurred in younger boys and was associated with a germ cell count that was usually normal and higher than the mean for the majority of cases. Although this finding was not identified in normal boys, its relevance to tumor risk remains completely unknown.

Updated analyses have clarified the nature of increased TGCT risk in the previously cryptorchid and contralateral descended testis (Wood and Elder, 2009; Banks et al, 2012; Trabert et al, 2013). A history of cryptorchidism is associated with a twofold to fivefold increased risk of testicular cancer, lower than historical estimates. This incidence correlates with the reported risk of ITGCNU of 2% to 3% in previously cryptorchid men (Giwerzman et al, 1989); a much lower risk (0% to 0.4%) was reported in children with nonsyndromic cryptorchidism (Cortes et al, 2001; Husmann, 2005). Men with a history of cryptorchidism comprise about 10% of those with TGCT. Tumors may occur in the contralateral descended testis of men with a history of unilateral cryptorchidism, but Wood and Elder (2009) concluded that the relative risk of only

1 to 2 indicates a level comparable to the general population that is not related to cryptorchidism per se. However, two meta-analyses suggest that the risk of tumor is increased in the contralateral testis, with odds ratios (ORs) of 1.7 (95% CI 1.01 to 2.98) and 1.5 (05% CI 0.9 to 2.6), respectively (Akre et al, 2009; Banks et al, 2012). In another meta-analysis, Walsh and colleagues determined that the relative risk of TGCT was 5.8 (95% CI 1.8 to 19.3) in men who underwent orchidopexy after age 10 to 11 as compared with those undergoing earlier correction (Walsh et al, 2007). Population-based data are conflicting, showing twice the risk of TGCT in patients undergoing orchidopexy at or after age 13 in some series (Pettersson et al, 2007; Trabert et al, 2013) but no age-dependent differences in another series (Myrup et al, 2007), possibly related to ascertainment bias. Review of tumor pathology in treated versus untreated cryptorchidism shows that seminoma is associated with persistently cryptorchid testes (74%) and nonseminoma is present in the majority of scrotal testes (63%) (Wood and Elder, 2009).

In a population-based study in Sweden, hypospadias (OR 2.25, 95% CI 1.17 to 4.32); inguinal hernia (OR 1.30, 95% CI 1.06 to 1.60), and other genital malformations (OR 1.90, 95% CI 1.00 to 3.63) were independent risk factors for TGCT, in addition to cryptorchidism (OR 3.16, 95% CI 2.45 to 3.96) (Trabert et al, 2013). Consistent with the researchers' previous studies, ORs were lower when cryptorchidism was diagnosed before (OR 2.76, 95% CI 2.09 to 3.65) versus after (OR 4.96, 95% CI 3.06 to 8.04) puberty, whereas the reverse was true for hypospadias and hernia, wherein associations were stronger at a younger age at presentation. These data provide stronger support for a link between hypospadias and TGCT, but the authors cautioned that they did not confirm the existence of common risk factors in TDS conditions (Trabert et al, 2013).

The risk of TGCT is even greater in some types of syndromic cryptorchidism, as in conditions associated with chromosomal defects or DSD (Cortes et al, 2001; Husmann, 2005). Husmann has recommended that biopsy be performed in these individuals and in boys older than 12 undergoing orchidopexy, although the age cutoff and usefulness of biopsy during pubertal orchidopexy has not been clearly defined. Orchiectomy should be considered the preferred treatment of cryptorchid testes in postpubertal males up to the age of 50 (Wood and Elder, 2009). Swerdloff and colleagues reported in a retrospective cohort study that testicular biopsy at orchidopexy was associated with an increased risk of future TGCT compared with orchidopexy without biopsy (RR 6.7, 95% CI 2.7 to 13.5), but the indications for biopsy in this series were not clearly known (Swerdloff et al, 1997). A subsequent report from a large Scandinavian cohort showed that universal biopsy did not appear to increase the risk for TGCT beyond what is expected for previously cryptorchid men (Møller et al, 1998).

Testicular microlithiasis, characterized by multiple spectral calcifications within the testicular parenchyma (Fig. 148-14), is more frequently present in men with ITGCNU or TGCT, but is also present in 5% to 10% of the normal population and in a similar

Figure 148-14. Associated sonographic abnormalities in boys with cryptorchidism. Ultrasound images from an 11-year-old boy with testicular asymmetry who underwent bilateral orchidopexies in infancy. A, Right microlithiasis. B, Ectasia of the left rete testis.

proportion of previously cryptorchid men (Patel et al, 2005; van Casteren et al, 2009). Although concern exists that the risk for TGCT may be higher when cryptorchidism coexists with microlithiasis in individual patients, no data exist to support this hypothesis and the appropriate follow-up strategy remains undefined. Even less well defined is the significance of microlithiasis in general, which is not clearly shown to be an independent risk factor for TGCT. A recent population-based analysis of the prevalence of microlithiasis in a series of primarily Caucasian boys shows that the prevalence is 4.2% and increases with age (Goede et al, 2009). In about half of these cases, the degree of microlithiasis was limited, defined as fewer than five lesions per testis, and not considered clinically significant. The general prevalence was 3.5% in boys with cryptorchidism and 6.4% in a series of 261 older boys (mean age 18.9) being followed after a diagnosis of acquired cryptorchidism

(Goede and Hack, 2012; van der Plas et al, 2013a). The occurrence of testicular tumors in boys with microlithiasis is rare and not yet reported in association with cryptorchidism (Goede and Hack, 2012). Other testicular abnormalities identified during ultrasound follow-up in males treated for cryptorchidism include ectasia of the rete testis (see Fig. 148-13) (Nistal et al, 1996) and intratesticular varicocele (Meij-de Vries et al, 2013). The significance of these entities in the context of cryptorchidism remains poorly defined. Although the U.S. Preventive Services Task Force does not recommend routine testicular self-examination in adolescents and adults because treatment for TGCT is highly effective, the recommendation does not include previously cryptorchid males (U.S. Preventive Services Task Force, 2011). Physicians should educate patients and their families about the risks of infertility and TGCT in cryptorchidism and should provide counsel about the potential benefits of testicular self-examination.

KEY POINTS

- Gonadal determination involves separate genetic pathways for development of testis and ovary. SRY is a master switch in males that regulates downstream testis-determining genes.
- Differentiation of gonocytes and Sertoli and Leydig cells occurs at 5 to 9 weeks' gestation, and the gubernaculum, the guide for testicular descent, appears at 7 weeks' gestation.
- Levels of the Leydig cell hormones testosterone and INSL3 peak at 14 to 17 weeks' gestation and are critical for testicular descent.
- Swelling of the gubernaculum, which starts in the second trimester, provides space for passage of the testis into the scrotum at 20 to 28 weeks' gestation.
- Cryptorchidism occurs in 1% to 4% of full-term male infants; both spontaneous descent (in the first few months of life, usually by 6 months) and reascent of testes may occur.
- The causes of cryptorchidism are largely unknown, but birth weight, gestational age, and genetic and environmental risk factors likely contribute to disease risk.
- The diagnosis of cryptorchidism may be acquired—that is, made in cases of apparent full descent at birth or after spontaneous descent of a cryptorchid testis—and may be more common in boys with retractile testes. Yearly testicular examinations are recommended.
- About 80% of undescended testes are palpable and 60% to 70% are unilateral.
- Many boys with nonsyndromic cryptorchidism have epididymal anomalies and a patent processus vaginalis, and some have reduced LH and/or testosterone levels during the postnatal surge.
- Orchidopexy is recommended for testes that remain undescended after 6 months of age; hormone therapy is not recommended.
- Laparoscopy is the procedure of choice, and imaging studies are rarely useful in the diagnosis and treatment of abdominal cryptorchidism.
- Sperm counts are reduced in at least 25% of formerly unilateral and the majority of formerly bilateral cryptorchid men, but paternity rates in the unilateral group are similar to those in control men.
- Ad spermatogonia counts may predict fertility potential in males with cryptorchidism.
- TGCT risk is two to five times higher in boys with cryptorchidism, especially after pubertal orchidopexy.

Female Genital Embryology

Evaluation and Classification of Female Genital Anomalies

Congenital Disorders of Female External Genitalia

Acquired Disorders of the Female External Genitalia

As with the other organ systems, genital development in the female occurs in an orderly fashion through multiple complex steps that result in an anatomically and functionally normal child in the vast majority of cases. However, errors in development can occur, from minor, clinically insignificant disorders to severe abnormalities that are devastating to the child and parents. The abnormalities may affect the external genitalia alone or in combination with internal genital anomalies, and in some they may involve other organ systems. This chapter briefly describes normal female urogenital development and then discusses anomalies that arise when abnormal development occurs. Genital ambiguity may be the initial finding in these disorders.

FEMALE GENITAL EMBRYOLOGY

A comprehensive description of genitourinary embryology can be found in Chapters 122 and 150. To foster a deeper understanding of the complex combination of anomalies that can occur in patients with external genital/vaginal anomalies, a brief review of relevant embryologic events is presented.

The cloaca is an endoderm-lined primordial organ that is first apparent at the beginning of the second week of gestation (Grosfeld, 1996). This structure, which represents a confluence of the primitive hindgut (dorsally) and the allantois (ventrally) just before the fourth week of gestation, receives the mesonephric ductal system. The urorectal septum, which first appears during the fourth week of development, serves to separate the urogenital sinus (ventrally) from the anal canal (dorsally) (Moore and Persaud, 1995). The urorectal septum actually consists of two components. The first is the Tournoux fold, which develops along the coronal plane in the angle between the allantois and the hindgut and grows in a caudal fashion toward the cloacal membrane. As this septum nears the cloacal membrane, infoldings of the lateral walls of the cloaca form Rathke plicae, which coalesce in the coronal midline and form the urorectal septum caudally. By weeks 6 to 7 of development the urorectal septum has fused with the cloacal membrane and divided it into a ventral urogenital membrane and a dorsal anal membrane. The fibromuscular node of tissue that results from contact of the septum with the cloacal membrane serves as a critical insertion site for the perineal muscles and as the dividing point of the primitive cloacal sphincter complex into anterior (urogenital diaphragm) and posterior (external anal sphincter) components. **The common ontogeny of these two sphincter complexes explains why the pudendal nerve supplies all of these muscles.**

While the urorectal anlage is undergoing division, the developing mesonephric ducts, which have contacted the cloaca, enter the urogenital sinus near the müllerian tubercle (Churchill et al, 1978). An offshoot of the mesonephric duct, the ureteric bud, extends cranially to induce development of the metanephric blastema. The terminal branch point of the ureteral bud from the mesonephric duct is later absorbed into the wall of the urogenital sinus. Proper incorporation of this complex results in the ureters opening at the lateral aspect of the trigone.

During this critical phase of development, paired müllerian ducts, which form from the coelomic epithelium, develop lateral to the mesonephric ducts and cross medially to fuse in the midline. The close proximity of these two ductal systems helps explain the common association of paramesonephric abnormalities and ipsilateral renal anomalies. The paired müllerian ducts then proceed caudally to join the urogenital sinus, where they produce an elevation called the *müllerian tubercle*. The caudal fusion of portions of these ducts normally leads to dissolution of the shared midline partition and the formation of a common uterovaginal canal, which, as the name implies, gives rise to the uterus, cervix, and proximal two thirds of the vagina. Failure of septal regression can result in a number of possible müllerian duct abnormalities.

As first delineated by Koff in 1933 (Koff, 1933), contact of the uterovaginal primordium with the urogenital sinus forms the müllerian tubercle, which in turn induces the formation of paired caudal endodermal outgrowths called sinovaginal bulbs. Evidence suggests that these outpouchings may in fact represent the terminal segments of the wolffian ducts (Bok and Drews, 1983). Regardless of origin, the cells within these sinovaginal bulbs then proliferate to form a cord of tissue that develops into a distal vaginal plate, which is later canalized in a caudal-to-cranial direction to form the distal aspect of the vagina (Fig. 149-1). The portion of the urogenital sinus distal to the müllerian tubercle subsequently undergoes exstrophy and everts to become the vestibule. As a result of this process, the urethra and vagina acquire separate openings in the vulva. The lumen of the vagina is separated from the cavity of the urogenital sinus by the hymen, an invagination of the posterior wall of the urogenital sinus. Rupture of the hymen should occur during the perinatal period.

Various cystic structures may form along the luminal aspect of the vagina. Remnants of the prostatic ductal system and the wolffian duct give rise to the paraurethral glands of Skene and Gardner, respectively. Outgrowths from the urogenital sinus form the greater vestibular glands of Bartholin, which are homologs of the bulbourethral glands in the male.

Figure 149-1. A to C, Formation of the vagina from the sinovaginal bulbs. (From Saler TW. Langman's medical embryology, 6th ed. Baltimore: Williams & Wilkins; 1990.)

Key events in skeletal formation occur concurrently with cloacal division and proper formation of the mesonephric and paramesonephric ductal systems (Churchill et al, 1978). The vertebrae develop in a craniocaudal direction, with the lower extremity limb buds developing from condensation of somites 25 through 29. These somites undergo critical differentiation from the fourth through the eighth weeks of development.

From the foregoing brief description of caudal embryology it should be evident that a disturbance in segmentation at the level of the caudal somites when the fetus is less than 10 mm (fourth to fifth weeks of human development) can affect many organ systems. In 1960, Duhamel (1961) described the association of these "coincidentally" occurring congenital malformations and introduced the term *caudal regression syndrome*. Laboratory data with teratogens support the concept that a key event occurs between the fourth and fifth weeks of gestation that results in an error in the simultaneous development of the terminal bowel, kidney, bladder, paramesonephric ductal system, and lumbosacral spine (Mesrobian et al, 1994). The actual inciting event remains unclear, although disordered mesodermal migration, reduced cellular proliferation, and premature apoptosis have been proposed as potential mechanisms (Kallen and Winberg, 1974; Alles and Sulik, 1993). Elements of the caudal regression syndrome are seen with increased frequency in infants of diabetic mothers, but the exact mechanism is still in question (Deuchar, 1978; Lynch et al, 1995). Specific gene deletions in the homeobox region of the mammalian genome (the region critical for proper mammalian spatial orientation and segmentation) have been shown to result in a constellation of anatomic findings, as predicted by Duhamel (Warot et al, 1997). Because differentiation of the somites progresses in a cranial-to-caudal direction, it would follow that the most complex anomalies (higher anorectal malformations) would occur as a result of aberrations at an earlier stage of development. This also helps explain the greater association of severe upper urinary tract malformations, internal genital duct abnormalities, and spinal anomalies in these patients than in those with less severe cases of imperforate anus.

Mesodermal disturbances are not limited to the caudal somites. As seen in the VATER (Vertebral defects, Anal atresia, Tracheoesophageal fistula with Esophageal atresia, and Radial and renal dysplasia) and MURCS (Müllerian duct aplasia, Renal aplasia, and Cervicothoracic Somite dysplasia) associations, mesodermally derived organs as cranial as the C1 vertebra and tracheoesophageal anlagen can be affected in association with congenital abnormalities of the mesonephric and paramesonephric ductal systems (Quan and Smith, 1973; Duncan et al, 1979).

KEY POINTS: FEMALE GENITAL EMBRYOLOGY

- The common ontogeny of the urogenital sphincter and the external anal sphincter explains why the pudendal nerve supplies both muscle complexes.
- The close proximity of the müllerian and wolffian ductal systems is responsible for the common association of paramesonephric abnormalities and ipsilateral renal anomalies.
- A disturbance in segmentation at the level of the caudal somites during the fourth or fifth weeks of development can result in a constellation of malformations involving the urogenital, skeletal, and gastrointestinal systems that are commonly referred to as the *caudal regression syndrome*.

EVALUATION AND CLASSIFICATION OF FEMALE GENITAL ANOMALIES

Structural anomalies of the vulva are numerous and varied. The differential diagnosis in the neonate and young child is broad and requires a thorough understanding of the diagnostic possibilities and a systematic evaluation. The age and racial background of the patient can help narrow the differential diagnosis, but physical examination remains the most useful tool for determining the specific pathology.

The physician must be sure to specifically reassure the girl that the examination will not be painful. With the child in the frog-leg position, the physician should note the size of the clitoris, the configuration of the hymen, the location of the urethra, and the character of the interlabial mass (e.g., smooth, lobulated, hemorrhagic). To aid in visualization, the labia majora can be gently grasped and pulled caudally and laterally to enable funneling of the introitus and vagina (the so-called pull-down maneuver) (Kaefer, 2010) (Fig. 149-2). Establishing the location of expected anatomic landmarks can facilitate determining the nature of a specific mass. In certain circumstances, the relationship of the mass to the vagina and urethra can be improved by gentle placement of a lubricated cotton applicator posteriorly or placement of a small feeding tube within the suspected urethral orifice, or both. Although an otoscope, nasal speculum, or pediatric vaginal speculum can be useful in evaluating the vagina while the patient is awake, complaints of vaginal origin (i.e., vaginal discharge or bleeding) are often best

investigated with a carefully performed examination and vaginoscopy under anesthesia. Renal-pelvic ultrasonography can be a useful adjunct in confirming or establishing the diagnosis in a few of these disorders.

Structural anomalies of the vagina can be grouped into three main categories: (1) those resulting from either hypoplasia or agenesis, (2) those caused by vertical fusion (canalization abnormalities resulting from abnormal contact of the müllerian

structures with the urogenital sinus), and (3) those resulting from lateral fusion (duplication). The clinical manifestations, physical findings, evaluation, and subsequent therapy vary considerably among these groups. Radiographic imaging is of central importance in determining the correct diagnosis. Ultrasonography is helpful not only in identifying the genital anatomy but also in screening for associated upper urinary tract abnormalities (Rosenberg et al, 1986; Fernandez et al, 1996). Magnetic resonance imaging (MRI) is considered by many to be the gold standard for defining müllerian anatomy (Fedeale et al, 1996; Russ et al, 1997; Lang et al, 1999). It is especially useful for determining the presence or absence of the cervix and the presence of functioning endometrium in complex anomalies. In complicated cases, additional information can be obtained by examination under anesthesia, vaginoscopy, hysteroscopy, and laparoscopy (Major et al, 1997). Obstructive anomalies typically require immediate intervention, but nonobstructive anomalies often do not require surgical intervention unless the patient has reached reproductive age and the condition affects intercourse or adversely affects fertility. Various systems have been proposed for the classification of these anomalies, with the system proposed by the American Society for Reproductive Medicine being the most inclusive (American Fertility Society, 1988).

CONGENITAL DISORDERS OF FEMALE EXTERNAL GENITALIA

Disorders of the Clitoris

Hypertrophied Clitoris

Clitoral hypertrophy is most commonly the result of excess androgenic metabolites arising secondary to an enzymatic defect in adrenal steroid synthesis (Fig. 149-3). The most commonly seen syndromes of congenital adrenal hyperplasia (CAH) result from a deficiency of either 21-hydroxylase or 11-hydroxylase. Some degree of clitoral enlargement can be appreciated in nearly every female patient with CAH. Although there is often concordance between the degree of clitoromegaly and the length of the common urogenital sinus, this does not always apply. Because the overwhelming majority of clitoral hypertrophy is secondary to CAH, any newborn noted to have this physical finding should undergo an evaluation of their serum electrolytes, 17-hydroxyprogesterone level, and karyotype. Replacement of glucocorticoids and mineralocorticoids will exert a negative feedback on the adrenal gland and thus eliminate further stimulation of the external genitalia from endogenously derived androgens. The role of surgery in this disorder is discussed elsewhere in this text.

Figure 149-2. A and B, Photographs of the vaginal pull-down procedure. To aid in visualization of the female introitus, the labia majora are gently grasped and pulled caudally and laterally to enable funneling of the vagina.

Figure 149-3. Clitoral hypertrophy in congenital adrenal hyperplasia.

Clitoral enlargement can result from other disorders. Endogenous androgen-producing tumors in the mother can result in stimulation of the fetal phallus. The presence of unilateral viable testicular tissue in a patient with Turner syndrome also has been reported (Haddad et al, 2003). Finally, local growth factor secretion from a neighboring plexiform neurofibroma in patients with neurofibromatosis has been reported on multiple occasions to result in clitoromegaly (Rink and Mitchell, 1983; Kearse and Ritchey, 1993; Kaefer et al, 1997; Yuksel et al, 2003; Cost et al, 2009).

Diminutive Clitoris
